Welcome

Welcome to this course. It is only a little introduction to Machine Learning.

The aim of Machine Learning is to build computer systems that can adapt to their environments and learn from experience. Learning techniques and methods from this field are successfully applied to a variety of learning tasks in a broad range of areas, including, for example, spam recognition, text classification, gene discovery, financial forecasting. The course will give an overview of many concepts, techniques, and algorithms in machine learning, beginning with topics such as linear regression and classification and ending up with topics such as kmeans and Expectation Maximization. The course will give the student the basic ideas and intuition behind these methods, as well as a more formal statistical and computational understanding. Students will have an opportunity to experiment with machine learning techniques in R and apply them to a selected problem.

Introduction

What is Machine Learning ?

What is Machine Learning?

Two definitions of Machine Learning are offered. Arthur Samuel described it as: “the field of study that gives computers the ability to learn without being explicitly programmed.” This is an older, informal definition.

Tom Mitchell provides a more modern definition: “A computer program is said to learn from experience E with respect to some class of tasks T and performance measure P , if its performance at tasks in T , as measured by P , improves with experience E .”

Machine Learning is also called Statistical Learning.

Example: playing checkers.

E = the experience of playing many games of checkers

T = the task of playing checkers.

P = the probability that the program will win the next game.

In general, any machine learning problem can be assigned to one of two broad classifications:

Supervised learning and Unsupervised learning.

Supervised Learning

Supervised Learning is probably the most common type of machine learning problem. Let's start with an example of what is it. Let's say we want to predict housing prices. We plot a data set and it looks like this.

Here on the horizontal axis, the size of different houses in square feet, and on the vertical axis, the price of different houses in thousands of dollars.

So. Given this data, let's say we own a house that is, say 750 square feet and hoping to sell the house and we want to know how much we can get for the house.

So how can the learning algorithm help?

One thing a learning algorithm might be able to do is put a straight line through the data or to “fit” a straight line to the data and, based on that, it looks like maybe the house can be sold for maybe about \$150,000.

But maybe this isn't the only learning algorithm we can use. There might be a better one. For example, instead of sending a straight line to the data, we might decide that it's better to fit a quadratic function or a second-order polynomial to this data.

If we do that, and make a prediction here, then it looks like, well, maybe we can sell the house for closer to \$200,000.

This is an example of a supervised learning algorithm.

The term supervised learning refers to the fact that we gave the algorithm a data set in which the “**right answers**” were given.

The example above is also called a regression problem. A regression problem is when we try to predict a **continuous** value output. Namely the price in the example.

Here's another supervised learning example. Let's say we want to look at medical records and try to predict

of a breast cancer as malignant or benign. If someone discovers a breast tumor, a lump in their breast, a malignant tumor is a tumor that is harmful and dangerous and a benign tumor is a tumor that is harmless. Let's see a collected data set and suppose in the data set we have the size of the tumor on the horizontal axis and on the vertical axis we plot one or zero, yes or no, whether or not these are examples of tumors we've seen before are malignant (which is one) or zero if not malignant or benign.

Breast cancer (malignant, benign)

In this data set we have five examples of benign tumors, and five examples of malignant tumors.

Let's say a person who tragically has a breast tumor, and let's say her breast tumor size is known (rose arrow in the following figure).

Breast cancer (malignant, benign)

The machine learning question is, can you estimate what is the probability that a tumor is malignant versus benign? To introduce a bit more terminology this is an example of a **classification** problem.

The term classification refers to the fact that here we're trying to predict a **discrete** value output: zero or one, malignant or benign. And it turns out that in classification problems sometimes you can have more than two values for the two possible values for the output.

In classification problems there is another way to plot this data. Let's use a slightly different set of symbols to plot this data. So if tumor size is going to be the attribute that we are going to use to predict malignancy

or benignness, we can also draw the data like this.

All we did was we took the data set on top and just mapped it down using different symbols. So instead of drawing crosses, we are now going to draw 0's for the benign tumors.

Now, in this example we use only one **feature** or one attribute, mainly, the tumor size in order to predict whether the tumor is malignant or benign.

In other machine learning problems we may have more than one feature.

Here's an example. Let's say that instead of just knowing the tumor size, we know both the age of the patients and the tumor size. In that case maybe the data set will look like this.

So, let's say a person who tragically has a tumor. And maybe, their tumor size and age falls around there (rose point):

So given a data set like this, what the learning algorithm might do is throw a straight line through the data to try to separate out the malignant tumors from the benign ones. And with this, hopefully we can decide that the person's tumor falls on this benign side and is therefore more likely to be benign than malignant.

In this example we had **two features**, namely, the age of the patient and the size of the tumor. In other machine learning problems we will often have more features.

Most interesting learning algorithms is a learning algorithm that can deal with, not just two or three or five features, but an **infinite number of features**. So how do you deal with an infinite number of features. How do you even store an infinite number of things on the computer when your computer is gonna run out of memory.

Unsupervised Learning

The second major type of machine learning problem is called Unsupervised Learning.

The difference between Unsupervised Learning and Supervised Learning is that in Supervised Learning we are told explicitly what is the so-called right answers (data are labeled).

In Unsupervised Learning, we're given data that doesn't have any labels or that all has the same label or really no labels. Like in this example:

Unsupervised Learning

So we're given the data set and we're not told what to do with it and we're not told what each data point is. Instead we're just told, here is a data set. Can you find some structure in the data?

Given this data set, an Unsupervised Learning algorithm might decide that the data lives in two different clusters.

Unsupervised Learning

This is called a **clustering** algorithm.

Here are two examples where Unsupervised Learning or clustering is used.

Social network analysis:

So given knowledge about which friends you email the most or given your Facebook friends or your Google+ circles, can we automatically identify which are cohesive groups of friends, also which are groups of people that all know each other?

Market segmentation:

Market segmentation

Many companies have huge databases of customer information. So, can you look at this customer data set and automatically discover market segments and automatically group your customers into different market segments so that you can automatically and more efficiently sell or market your different market segments together?

This is Unsupervised Learning because we have all this customer data, but we don't know in advance what are the market segments and for the customers in our data set, we don't know in advance who is in market segment one, who is in market segment two, and so on. But we have to let the algorithm discover all this just from the data.

Part I

Supervised Learning

Part II

Regression

Chapter 1

Linear Regression

1.1 Notation

In general, we will let x_{ij} represent the value of the j th variable for the i th observation, where $i = 1, 2, \dots, n$ and $j = 1, 2, \dots, p$. We will use i to index the samples or observations (from 1 to n) and j will be used to index the variables (or features) (from 1 to p). We let \mathbf{X} denote a $n \times p$ matrix whose (i, j) th element is x_{ij} . That is,

$$\mathbf{X} = \begin{pmatrix} x_{11} & x_{12} & x_{13} & \dots & x_{1p} \\ x_{21} & x_{22} & x_{23} & \dots & x_{2p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_{n1} & x_{n2} & x_{n3} & \dots & x_{np} \end{pmatrix}$$

Note that it is useful to visualize \mathbf{X} as a spreadsheet of numbers with n rows and p columns. We will write the rows of \mathbf{X} as x_1, x_2, \dots, x_n . Here x_i is a vector of length p , containing the p variable measurements for the i th observation. That is,

$$x_i = \begin{pmatrix} x_{i1} \\ x_{i2} \\ \vdots \\ x_{ip} \end{pmatrix}$$

(Vectors are by default represented as columns.)

We will write the columns of \mathbf{X} as $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p$. Each is a vector of length n . That is,

$$\mathbf{x}_j = \begin{pmatrix} \mathbf{x}_{1j} \\ \mathbf{x}_{2j} \\ \vdots \\ \mathbf{x}_{nj} \end{pmatrix}$$

Using this notation, the matrix \mathbf{X} can be written as

$$\mathbf{X} = (\mathbf{x}_1 \mathbf{x}_2 \dots \mathbf{x}_p)$$

or

$$\mathbf{X} = \begin{pmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_n^T \end{pmatrix}$$

The T notation denotes the transpose of a matrix or vector.

We use y_i to denote the i th observation of the variable on which we wish to make predictions. We write the set of all n observations in vector form as

$$\mathbf{y} = \begin{pmatrix} y_1^T \\ y_2^T \\ \vdots \\ y_n^T \end{pmatrix}$$

Then the observed data consists of $\{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\}$, where each x_i is a vector of length p . (If $p = 1$, then x_i is simply a scalar).

1.2 Model Representation

Let's consider the example about predicting housing prices. We're going to use this data set as an example,

Figure 1.1:

Suppose that there is a person trying to sell a house of size 1250 square feet and he wants to know how much he might be able to sell the house for. One thing we could do is fit a model. Maybe fit a straight line to this data. Looks something like this,

Figure 1.2:

and based on that, maybe he can sell the house for around \$220,000. Recall that this is an example of a supervised learning algorithm. And it's supervised learning because we're given the "right answer" for each of our examples. More precisely, this is an example of a regression problem where the term regression refers to the fact that we are predicting a real-valued output namely the price.

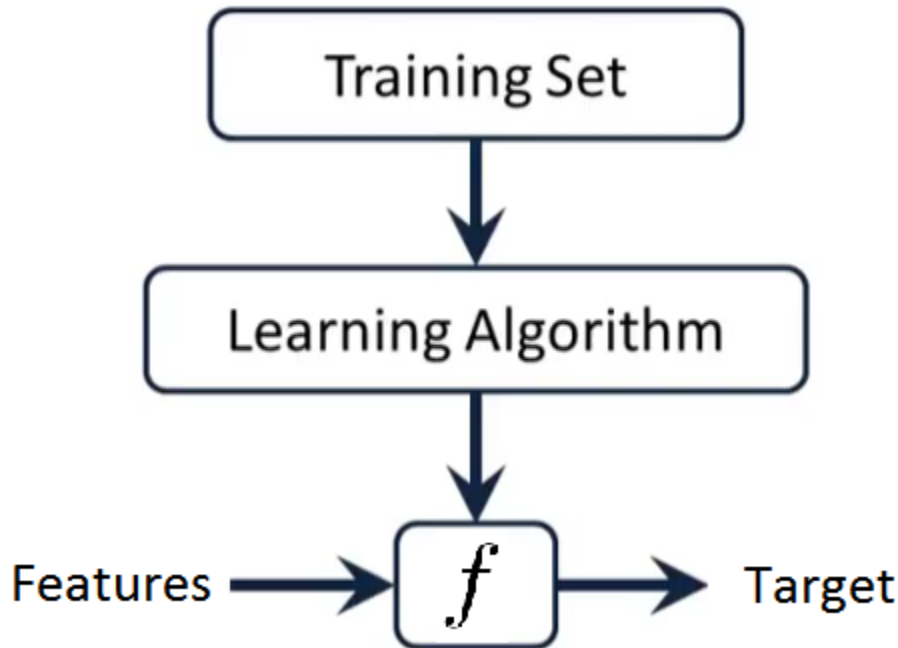

More formally, in supervised learning, we have a data set and this data set is called a **training set**. So for housing prices example, we have a training set of different housing prices and our job is to learn from this data how to predict prices of the houses.

Let's define some notation from this data set:

- The size of the house is the input variable.
- The house price is the output variable.
- The input variables are typically denoted using the variable symbol X ,
- The inputs go by different names, such as predictors, independent variables, features, predictor or sometimes just variables.
- The output variable is often called the response, dependent variable or target, and is typically denoted using the symbol Y .
- (x_i, y_i) is the i th training example.
- The set of $\{(x_i, y_i)\}$ is the training set.
- n is the number of training examples.

So here's how this supervised learning algorithm works. Suppose that we observe a quantitative response Y and p different predictors, X_1, X_2, \dots, X_p . We assume that there is some relationship between Y and $X = (X_1, X_2, \dots, X_p)$, which can be written in the very general form

$$Y = f(X) + \epsilon$$

Here f is some fixed but unknown function of X_1, X_2, \dots, X_p , and ϵ is a random error term, which is independent of X and has mean zero. The f function is also called hypothesis in Machine Learning. In general, the function f may involve more than one input variable. In essence, Supervised Learning refers to a set of approaches for estimating f .

1.3 Why Estimate f ?

There are two main reasons that we may wish to estimate f : prediction and inference.

Prediction

In many situations, a set of inputs X are readily available, but the output Y cannot be easily obtained. In this setting, since the error term averages to zero, we can predict Y using

$$\hat{Y} = \hat{f}(X)$$

where \hat{f} represents our estimate for f , and \hat{Y} represents the resulting prediction for Y . Like in the example above about predicting housing prices.

We can measure the accuracy of \hat{Y} by using a **cost function**. In the regression models, the most commonly-used measure is the mean squared error (MSE), given by

$$MSE = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{f}(x_i))^2$$

Inference

We are often interested in understanding the way that Y is affected as X_1, X_2, \dots, X_p change. In this situation we wish to estimate f , but our goal is not necessarily to make predictions for Y . We instead want to understand the relationship between X and Y , or more specifically, to understand how Y changes as a function of X_1, X_2, \dots, X_p . In this case, one may be interested in answering the following questions:

- Which predictors are associated with the response?
- What is the relationship between the response and each predictor?
- Can the relationship between Y and each predictor be adequately summarized using a linear equation, or is the relationship more complicated?

1.4 Simple Linear Regression Model

Simple linear regression is a very straightforward approach for predicting a quantitative response Y on the basis of a single predictor variable X . It assumes that there is approximately a linear relationship between X and Y . Mathematically, we can write this linear relationship as

$$Y = \beta_0 + \beta_1 X + \epsilon$$

$$Y \approx \beta_0 + \beta_1 X$$

where β_0 and β_1 are two unknown constants that represent the intercept and slope, also known as *coefficients* or parameters, and ϵ is the error term.

Given some estimates $\hat{\beta}_0$ and $\hat{\beta}_1$ for the model coefficients, we predict future inputs x using

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x$$

where \hat{y} indicates a prediction of Y on the basis of $X = x$. The hat symbol, $\hat{\cdot}$, denotes an estimated value.

1.5 Estimating the Coefficients

Let $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i$ be the prediction for Y based on the i th value of X . Then $e_i = y_i - \hat{y}_i$ represents the i th *residual*.

We define the *residual sum of squares* (RSS) as

$$\begin{aligned} RSS &= e_1^2 + e_2^2 + \dots + e_n^2 \\ &= \sum_{i=1}^n e_i^2 \end{aligned}$$

or equivalently as

$$\begin{aligned} RSS &= (y_1 - \hat{\beta}_0 - \hat{\beta}_1 x_1)^2 + (y_2 - \hat{\beta}_0 - \hat{\beta}_1 x_2)^2 + \dots + (y_n - \hat{\beta}_0 - \hat{\beta}_1 x_n)^2 \\ &= \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2 \end{aligned}$$

The least squares approach chooses $\hat{\beta}_0$ and $\hat{\beta}_1$ to minimize the RSS. The minimizing values can be shown to be

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2} = \frac{s_{xy}}{s_x^2}$$

and

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x}$$

where:

- $\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$ is the sample mean.
- $s_x^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2$ is the sample variance. The sample standard deviation is $s_x = \sqrt{s_x^2}$.
- $s_{xy} = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})$ is the sample covariance. It measures the degree of linear association between x_1, \dots, x_n and y_1, \dots, y_n . Once scaled by $s_x s_y$, it gives the sample correlation coefficient, $r_{xy} = \frac{s_{xy}}{s_x s_y}$.

Click here to see the influence of the distance employed in the sum of squares. Try to minimize the sum of squares for the different datasets. The choices of intercept and slope that minimize the sum of squared distances for a kind of distance are not the optimal for a different kind of distance.

1.6 Assessing the Accuracy of the Coefficient Estimates

The standard error of an estimator reflects how it varies under repeated sampling. We have

$$\begin{aligned} \text{SE}(\hat{\beta}_1)^2 &= \frac{\sigma^2}{\sum_{i=1}^n (x_i - \bar{x})^2} \\ \text{SE}(\hat{\beta}_0)^2 &= \sigma^2 \left[\frac{1}{n} + \frac{\bar{x}^2}{\sum_{i=1}^n (x_i - \bar{x})^2} \right] \end{aligned}$$

where $\sigma^2 = \text{Var}(\epsilon)$

In general, σ^2 is known, but can be estimated from the data. The estimate of σ is known as the residual standard error, and is given by

$$\text{RSE} = \sqrt{\frac{\text{RSS}}{(n-2)}}$$

These standard errors can be used to compute confidence intervals. A 95% confidence interval is defined as a range of values such that with 95% probability, the range will contain the true unknown value of the parameter. It has the form

$$\hat{\beta}_1 \pm 2 \cdot \text{SE}(\hat{\beta}_1)$$

That is, there is approximately a 95% chance that the interval

$$\left[\hat{\beta}_1 - 2 \cdot \text{SE}(\hat{\beta}_1), \hat{\beta}_1 + 2 \cdot \text{SE}(\hat{\beta}_1) \right]$$

will contain the true value of β_1 . Similarly, a confidence interval for β_0 approximately takes the form

$$\hat{\beta}_0 \pm 2 \cdot \text{SE}(\hat{\beta}_0)$$

Hypothesis testing

Standard errors can also be used to perform hypothesis tests on the coefficients. The most common hypothesis test involves testing the null hypothesis of

$$H_0 : \text{There is no relationship between } X \text{ and } Y$$

versus the alternative hypothesis

$$H_1 : \text{There is some relationship between } X \text{ and } Y$$

Mathematically, this corresponds to testing

$$H_0 : \beta_1 = 0$$

versus

$$H_1 : \beta_1 \neq 0$$

since if $\beta_1 = 0$ then the simple linear regression model reduces to $Y = \beta_0 + \epsilon$, and X is not associated with Y .

To test the null hypothesis H_0 , we compute a ***t-statistic***, given by

$$t = \frac{\hat{\beta}_1 - 0}{\text{SE}(\hat{\beta}_1)}$$

This will have a t -distribution (Student) with $n - 2$ degrees of freedom, assuming $\beta_1 = 0$.

Using statistical software, it is easy to compute the probability of observing any value equal to $|t|$ or larger. We call this probability the ***p-value***.

If p -value is small enough (typically under 0.01 (1% error) or 0.05 (5% error)) we reject the null hypothesis, that is we declare a relationship to exist between X and Y .

1.7 ANOVA and model fit

1.7.1 ANOVA

In this section we will see how the variance of Y is decomposed into two parts, each one corresponding to the regression and to the error, respectively. This decomposition is called the ANalysis Of VAriance (ANOVA).

Before explaining ANOVA, it is important to recall an interesting result: the mean of the fitted values $\hat{Y}_1, \dots, \hat{Y}_n$ is the mean of Y_1, \dots, Y_n . This is easily seen if we plug-in the expression of $\hat{\beta}_0$:

$$\frac{1}{n} \sum_{i=1}^n \hat{Y}_i = \frac{1}{n} \sum_{i=1}^n (\hat{\beta}_0 + \hat{\beta}_1 X_i) = \hat{\beta}_0 + \hat{\beta}_1 \bar{X} = (\bar{Y} - \hat{\beta}_1 \bar{X}) + \hat{\beta}_1 \bar{X} = \bar{Y}.$$

The ANOVA decomposition considers the following measures of variation related with the response:

- $SST = \sum_{i=1}^n (Y_i - \bar{Y})^2$, the **total sum of squares**. This is the total variation of Y_1, \dots, Y_n , since $SST = ns_y^2$, where s_y^2 is the sample variance of Y_1, \dots, Y_n .
- $SSR = \sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2$, the **regression sum of squares**¹. This is the variation explained by the regression line, that is, the variation from \bar{Y} that is explained by the estimated conditional mean $\hat{Y}_i = \hat{\beta}_0 + \hat{\beta}_1 X_i$. $SSR = ns_{\hat{y}}^2$, where $s_{\hat{y}}^2$ is the sample variance of $\hat{Y}_1, \dots, \hat{Y}_n$.
- $SSE = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2$, the **sum of squared errors**². Is the variation around the conditional mean. Recall that $SSE = \sum_{i=1}^n \hat{\varepsilon}_i^2 = (n-2)\hat{\sigma}^2$, where $\hat{\sigma}^2$ is the sample variance of $\hat{\varepsilon}_1, \dots, \hat{\varepsilon}_n$.

The ANOVA decomposition is

$$\underbrace{SST}_{\text{Variation of } Y'_i s} = \underbrace{SSR}_{\text{Variation of } \hat{Y}'_i s} + \underbrace{SSE}_{\text{Variation of } \hat{\varepsilon}'_i s}$$

The graphical interpretation of this equation is shown in the following figures.

¹Recall that SSR is different from RSS (Residual Sum of Squares)

²Recall that SSE and RSS (for $(\hat{\beta}_0, \hat{\beta}_1)$) are just different names for referring to the same quantity: $SSE = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 = \sum_{i=1}^n (Y_i - \hat{\beta}_0 - \hat{\beta}_1 X_i)^2 = RSS(\hat{\beta}_0, \hat{\beta}_1)$.

Figure 1.3: Visualization of the ANOVA decomposition. SST measures the variation of Y_1, \dots, Y_n with respect to \bar{Y} . SSR measures the variation with respect to the conditional means, $\hat{\beta}_0 + \hat{\beta}_1 X_i$. SSE collects the variation of the residuals.

Click here to see the ANOVA decomposition and its dependence on σ^2 and $\hat{\sigma}^2$.

The ANOVA table summarizes the decomposition of the variance. Here is given in the layout employed by R.

	Degrees of freedom	Sum Squares	Mean Squares	F -value	p -value
Predictor	1	SSR	$\frac{SSR}{1}$	$\frac{SSR/1}{SSE/(n-2)}$	p
Residuals	$n - 2$	SSE	$\frac{SSE}{n-2}$		

The `anova` function in R takes a model as an input and returns the ANOVA table.

The “ F -value” of the ANOVA table represents the value of the F -statistic $\frac{SSR/1}{SSE/(n-2)}$. This statistic is employed to test

$$H_0 : \beta_1 = 0 \quad \text{vs.} \quad H_1 : \beta_1 \neq 0,$$

that is, the hypothesis of no linear dependence of Y on X . The result of this test is completely equivalent to the t -test for β_1 that we saw previously in the Hypothesis testing (this is something specific for simple linear regression – the F -test will not be equivalent to the t -test for β_1 in the Multiple Linear Regression).

It happens that

$$F = \frac{SSR/1}{SSE/(n-2)} \stackrel{H_0}{\sim} F_{1,n-2},$$

where $F_{1,n-2}$ is the Snedecor’s F distribution³ with 1 and $n - 2$ degrees of freedom.

If H_0 is true, then F is expected to be small since SSR will be close to zero. The p -value of this test is the same as the p -value of the t -test for $H_0 : \beta_1 = 0$.

1.7.2 The R^2 Statistic

To calculate R^2 , we use the formula

$$R^2 = \frac{TSS - RSS}{TSS} = 1 - \frac{RSS}{TSS}$$

where $TSS = \sum (y_i - \bar{y})^2$ is the total sum of squared.

R^2 measures the proportion of variability in Y that can be explained using X . An R^2 statistic that is close to 1 indicates that a large proportion of the variability in the response has been explained by the regression. A number near 0 indicates that the regression did not explain much of the variability in the response; this might occur because the linear model is wrong, or the inherent error σ^2 is high, or both.

It can be shown that in this simple linear regression setting that $R^2 = r^2$, where r is the correlation between X and Y :

³The $F_{n,m}$ distribution arises as the quotient of two independent random variables χ_n^2 and χ_m^2 , $\frac{\chi_n^2/n}{\chi_m^2/m}$.

$$r = \frac{\text{cov}(X, Y)}{\sigma_X \sigma_Y}$$

R^2 does not measure the correctness of a linear model but its **usefulness** (for prediction, for explaining the variance of Y), assuming the model is correct.

Trusting blindly the R^2 can lead to catastrophic conclusions, since the model may not be correct.

So remember:

A large R^2 means nothing if the **assumptions of the model do not hold**. R^2 is the proportion of variance of Y explained by X , but, of course, only when the linear model is correct.

PW 1

1.8 Some R basics

1.8.1 Basic Commands

R uses functions to perform operations. To run a function called `funcname`, we type `funcname(input1, input2)`, where the inputs (or arguments) `input1` and `input2` tell R how to run the function. A function can have any number of inputs. For example, to create a vector of numbers, we use the function `c()` (for concatenate).

```
x <- c(1,3,2,5)
x
#ans> [1] 1 3 2 5
```

Note that the `>` is not part of the command; rather, it is printed by R to indicate that it is ready for another command to be entered. We can also save things using `=` rather than `<-`. Note that the answer in the code above is followed by `#ans>` while in the R console it is not.

```
x = c(1,6,2)
x
#ans> [1] 1 6 2
y = c(1,4,3)
length(x)
#ans> [1] 3
length(y)
#ans> [1] 3
x+y
#ans> [1] 2 10 5
```

Hitting the up arrow multiple times will display the previous commands, which can then be edited. This is useful since one often wishes to repeat a similar command.

The `ls()` function allows us to look at a list of all of the objects, such as `ls()` as data and functions, that we have saved so far. The `rm()` function can be used to delete any object that we don't want.

```
ls()
#ans> [1] "x" "y"
rm(x)
ls()
#ans> [1] "y"
```

1.8.2 Vectors

```
# A handy way of creating sequences is the operator :
# Sequence from 1 to 5
1:5
#ans> [1] 1 2 3 4 5

# Storing some vectors
vec <- c(-4.12, 0, 1.1, 1, 3, 4)
vec
#ans> [1] -4.12 0.00 1.10 1.00 3.00 4.00

# Entry-wise operations
vec + 1
#ans> [1] -3.12 1.00 2.10 2.00 4.00 5.00
vec^2
#ans> [1] 16.97 0.00 1.21 1.00 9.00 16.00

# If you want to access a position of a vector, use [position]
vec[6]
#ans> [1] 4

# You also can change elements
vec[2] <- -1
vec
#ans> [1] -4.12 -1.00 1.10 1.00 3.00 4.00

# If you want to access all the elements except a position, use [-position]
vec[-2]
#ans> [1] -4.12 1.10 1.00 3.00 4.00

# Also with vectors as indexes
vec[1:2]
#ans> [1] -4.12 -1.00

# And also
vec[-c(1, 2)]
#ans> [1] 1.1 1.0 3.0 4.0
```

Do the following:

- Create the vector $x = (1, 7, 3, 4)$.
- Create the vector $y = (100, 99, 98, \dots, 2, 1)$.
- Compute $x_3 + y_4$ and $\cos(x_3) + \sin(x_2)e^{-y_2}$. (Answers: 100, -0.9899925)
- Set $x_3 = 0$ and $y_2 = -1$. Recompute the previous expressions. (Answers: 97, 2.785875)
- Index y by $x + 1$ and store it as z . What is the output? (Answer: z is $c(-1, 93, 100, 96)$)

1.8.3 Matrices, data frames and lists

```
# A matrix is an array of vectors
A <- matrix(1:4, nrow = 2, ncol = 2)
```

```

A
#ans>      [,1] [,2]
#ans> [1,]    1    3
#ans> [2,]    2    4

# Another matrix
B <- matrix(1:4, nrow = 2, ncol = 2, byrow = TRUE)
B
#ans>      [,1] [,2]
#ans> [1,]    1    2
#ans> [2,]    3    4

# Binding by rows or columns
rbind(1:3, 4:6)
#ans>      [,1] [,2] [,3]
#ans> [1,]    1    2    3
#ans> [2,]    4    5    6
cbind(1:3, 4:6)
#ans>      [,1] [,2]
#ans> [1,]    1    4
#ans> [2,]    2    5
#ans> [3,]    3    6

# Entry-wise operations
A + 1
#ans>      [,1] [,2]
#ans> [1,]    2    4
#ans> [2,]    3    5
A * B
#ans>      [,1] [,2]
#ans> [1,]    1    6
#ans> [2,]    6   16

# Accessing elements
A[2, 1] # Element (2, 1)
#ans> [1] 2
A[1, ] # First row
#ans> [1] 1 3
A[, 2] # First column
#ans> [1] 3 4

# A data frame is a matrix with column names
# Useful when you have multiple variables
myDf <- data.frame(var1 = 1:2, var2 = 3:4)
myDf
#ans>   var1 var2
#ans> 1     1    3
#ans> 2     2    4

# You can change names
names(myDf) <- c("newname1", "newname2")
myDf
#ans> newname1 newname2

```

```

#ans> 1      1      3
#ans> 2      2      4

# The nice thing is that you can access variables by its name with the $ operator
myDf$newname1
#ans> [1] 1 2

# And create new variables also (it has to be of the same
# length as the rest of variables)
myDf$myNewVariable <- c(0, 1)
myDf
#ans>   newname1 newname2 myNewVariable
#ans> 1         1         3             0
#ans> 2         2         4             1

# A list is a collection of arbitrary variables
myList <- list(vec = vec, A = A, myDf = myDf)

# Access elements by names
myList$vec
#ans> [1] -4.12 -1.00  1.10  1.00  3.00  4.00
myList$A
#ans>      [,1] [,2]
#ans> [1,]    1    3
#ans> [2,]    2    4
myList$myDf
#ans>   newname1 newname2 myNewVariable
#ans> 1         1         3             0
#ans> 2         2         4             1

# Reveal the structure of an object
str(myList)
#ans> List of 3
#ans> $ vec : num [1:6] -4.12 -1 1.1 1 3 4
#ans> $ A   : int [1:2, 1:2] 1 2 3 4
#ans> $ myDf:'data.frame': 2 obs. of  3 variables:
#ans> ..$ newname1      : int [1:2] 1 2
#ans> ..$ newname2      : int [1:2] 3 4
#ans> ..$ myNewVariable: num [1:2] 0 1
str(myDf)
#ans> 'data.frame': 2 obs. of  3 variables:
#ans> $ newname1      : int  1 2
#ans> $ newname2      : int  3 4
#ans> $ myNewVariable: num  0 1

# A less lengthy output
names(myList)
#ans> [1] "vec"  "A"    "myDf"

```

1.8.4 Graphics

The `plot()` function is the primary way to plot data in R. For instance, `plot(x,y)` produces a scatterplot of the numbers in `x` versus the numbers in `y`. There are many additional options that can be passed in to the `plot()` function. For example, passing in the argument `xlab` will result in a label on the `x`-axis. To find out more information about the `plot()` function, type `?plot`.

```
x=rnorm(100)
# The rnorm() function generates a vector of random normal variables,
# rnorm() with first argument n the sample size. Each time we call this
# function, we will get a different answer.
y=rnorm(100)
plot(x,y)
```

```
# with titles
plot(x,y,xlab="this is the x-axis",ylab="this is the y-axis",
main="Plot of X vs Y")
```

1.8.5 Distributions

```
# R allows to sample [r], compute density/probability mass [d],
# compute distribution function [p] and compute quantiles [q] for several
# continuous and discrete distributions. The format employed is [rdpq]name,
# where name stands for:
# - norm -> Normal
# - unif -> Uniform
# - exp -> Exponential
# - t -> Student's t
# - f -> Snedecor's F (Fisher)
# - chisq -> Chi squared
# - pois -> Poisson
# - binom -> Binomial
# More distributions: ?Distributions

# Sampling from a Normal - 100 random points from a N(0, 1)
rnorm(n = 10, mean = 0, sd = 1)
#ans> [1] 0.7474 1.0810 -1.0250 -0.1529 -0.0324 0.1698 -0.8135 -0.2311
#ans> [9] -0.7398 -0.2366

# If you want to have always the same result, set the seed of the random number
# generator
set.seed(45678)
rnorm(n = 10, mean = 0, sd = 1)
#ans> [1] 1.440 -0.720 0.671 -0.422 0.378 -1.667 -0.508 0.443 -1.799 -0.618

# Plotting the density of a N(0, 1) - the Gauss bell
x <- seq(-4, 4, l = 100)
y <- dnorm(x = x, mean = 0, sd = 1)
plot(x, y, type = "l")
```

```
# Plotting the distribution function of a N(0, 1)
x <- seq(-4, 4, l = 100)
y <- pnorm(q = x, mean = 0, sd = 1)
```

```
plot(x, y, type = "l", lwd = 3, main="The distribution function of a N(0, 1)")
```

```
# Computing the 95% quantile for a N(0, 1)
qnorm(p = 0.95, mean = 0, sd = 1)
#ans> [1] 1.64

# All distributions have the same syntax: rname(n,...), dname(x,...), dname(p,...)
# and qname(p,...), but the parameters in ... change. Look them in ?Distributions
# For example, here is que same for the uniform distribution

# Sampling from a U(0, 1)
set.seed(45678)
runif(n = 10, min = 0, max = 1)
#ans> [1] 0.9251 0.3340 0.2359 0.3366 0.7489 0.9327 0.3365 0.2246 0.6474 0.0808

# Plotting the density of a U(0, 1)
x <- seq(-2, 2, l = 100)
y <- dunif(x = x, min = 0, max = 1)
plot(x, y, type = "l")
```

```
# Computing the 95% quantile for a U(0, 1)
qunif(p = 0.95, min = 0, max = 1)
#ans> [1] 0.95
```

Do the following:

- Compute the 90%, 95% and 99% quantiles of a F distribution with $df1 = 1$ and $df2 = 5$. (Answer: `c(4.060420, 6.607891, 16.258177)`)
- Sample 100 points from a Poisson with $\lambda = 5$.
- Plot the density of a t distribution with $df = 1$ (use a sequence spanning from -4 to 4). Add lines of different colors with the densities for $df = 5$, $df = 10$, $df = 50$ and $df = 100$.

1.8.6 Working directory

Your working directory is the folder on your computer in which you are currently working. When you ask R to open a certain file, it will look in the working directory for this file, and when you tell R to save a data file or figure, it will save it in the working directory.

To set your working directory within RStudio you can go to **Tools / Set working directory**, or use the command `setwd()`, we put the complete path of the directory between the brackets, do not forget to put the path into quotation marks `"`.

To know the actual working directory we use `getwd()`.

1.8.7 Loading Data

The `read.table()` function is one of the primary ways to import a data set into R. The help file `?read.table()` contains details about how to use this function. We can use the function `write.table()` to export data.

Next we will show how to load the data set `Auto.data`.

```
Auto=read.table("Auto.data",header=T,na.strings = "?")
# For this file we needed to tell R that the first row is the
# names of the variables.
```

```
# na.strings tells R that any time it sees a particular character
# or set of characters (such as a question mark), it should be
# treated as a missing element of the data matrix.
```

- If the file is of csv format, we use `read.csv`.
- Always try to look to the file before importing it to R (Open it in a text editor. See for example if the first row contains the variables names, if the columns are separated by `,` or `;` or `..`
- For text editors, I suggest `Sublime Text` or `Atom`.

```
dim(Auto) # To see the dimensions of the data set
#ans> [1] 397 9
nrow(Auto) # To see the number of rows
#ans> [1] 397
ncol(Auto) # To see the number of columns
#ans> [1] 9
Auto[1:4,] # The first 4 rows of the data set
#ans> mpg cylinders displacement horsepower weight acceleration year origin
#ans> 1 18 8 307 130 3504 12.0 70 1
#ans> 2 15 8 350 165 3693 11.5 70 1
#ans> 3 18 8 318 150 3436 11.0 70 1
#ans> 4 16 8 304 150 3433 12.0 70 1
#ans> name
#ans> 1 chevrolet chevelle malibu
#ans> 2 buick skylark 320
#ans> 3 plymouth satellite
#ans> 4 amc rebel sst

# Once the data are loaded correctly, we can use names()
# to check the variable names.
names(Auto)
#ans> [1] "mpg" "cylinders" "displacement" "horsepower"
#ans> [5] "weight" "acceleration" "year" "origin"
#ans> [9] "name"
```

Take a look at this (very) short introduction to R. It can be useful.

1.9 Regression

1.9.1 The `lm` function

We are going to employ the EU dataset. The EU dataset contains 28 rows with the member states of the European Union (Country), the number of seats assigned under different years (Seats2011, Seats2014), the Cambridge Compromise apportionment (CamCom2011), and the countries population (Population2010,Population2013).

```
# Load the dataset, when we load an .RData using load()
# function we do not attribute it to a name like we did
# when we used read.table() or when we use read.csv()
```

```
load("EU.RData")
```

There is two ways to tell R where is the file you want to load/use/import or where to save a file when you write/export/save :

1. write the complete path of the files.
2. set a working directory and put the files in it.

```
# lm (for linear model) has the syntax:
# lm(formula = response ~ predictor, data = data)
# The response is the y in the model. The predictor is x.
# For example (after loading the EU dataset)
mod <- lm(formula = Seats2011 ~ Population2010, data = EU)

# We have saved the linear model into mod, which now contains all the output of lm
# You can see it by typing
mod
#ans>
#ans> Call:
#ans> lm(formula = Seats2011 ~ Population2010, data = EU)
#ans>
#ans> Coefficients:
#ans>      (Intercept)  Population2010
#ans>          7.91e+00          1.08e-06

# mod is indeed a list of objects whose names are
names(mod)
#ans> [1] "coefficients" "residuals"      "effects"        "rank"
#ans> [5] "fitted.values" "assign"          "qr"             "df.residual"
#ans> [9] "na.action"     "xlevels"         "call"           "terms"
#ans> [13] "model"

# We can access these elements by $
# For example
mod$coefficients
#ans>      (Intercept)  Population2010
#ans>          7.91e+00          1.08e-06

# The residuals
mod$residuals

```

The following table contains a handy cheat sheet of equivalences between R code and some of the statistical concepts associated to linear regression.

R	Statistical concept
x	Predictor X_1, \dots, X_n
y	Response Y_1, \dots, Y_n
data <- data.frame(x = x, y = y)	Sample $(X_1, Y_1), \dots, (X_n, Y_n)$
model <- lm(y ~ x, data = data)	Fitted linear model
model\$coefficients	Fitted coefficients $\hat{\beta}_0, \hat{\beta}_1$
model\$residuals	Fitted residuals $\hat{\varepsilon}_1, \dots, \hat{\varepsilon}_n$
model\$fitted.values	Fitted values $\hat{Y}_1, \dots, \hat{Y}_n$
model\$df.residual	Degrees of freedom $n - 2$
summaryModel <- summary(model)	Summary of the fitted linear model
summaryModel\$sigma	Fitted residual standard deviation $\hat{\sigma}$
summaryModel\$r.squared	Coefficient of determination R^2

R	Statistical concept
<code>summaryModel\$fstatistic</code>	F -test
<code>anova(model)</code>	ANOVA table

Do the following:

- Download The ‘EU’ dataset from here as an `.RData` file and load it using the function `load`.
- Compute the regression of `CamCom2011` into `Population2010`. Save that model as the variable `myModel`.
- Access the objects `residuals` and `coefficients` of `myModel`.
- Compute the summary of `myModel` and store it as the variable `summaryMyModel`.
- Access the object `sigma` of `myModel`.

1.9.2 Predicting House Value: Boston dataset

We are going to use a dataset called Boston which is part of the `MASS` package. It records the median value of houses for 506 neighborhoods around Boston. Our task is to predict the median house value (`medv`) using only one predictor (`lstat`: percent of households with low socioeconomic status).

```
# First, install the MASS package using the command: install.packages("MASS")

# load MASS package
library(MASS)

# Check the dimensions of the Boston dataset
dim(Boston)
#ans> [1] 506 14
```

STEP 1: Split the dataset

```
# Split the data by using the first 400 observations as the training
# data and the remaining as the testing data
train = 1:400
test = -train

# Specify that we are going to use only two variables (lstat and medv)
variables = which(names(Boston) == c("lstat", "medv"))
training_data = Boston[train, variables]
testing_data = Boston[test, variables]

# Check the dimensions of the new dataset
dim(training_data)
#ans> [1] 400 2
```

STEP 2: Check for Linearity

In order to perform linear regression in R, we will use the function `lm()` to fit a simple linear regression with `medv` as the response (dependent variable) and `lstat` as the predictor or independent variable, and then save it in `model`.

But before we run our model, let's visually check if the relationship between `x` and `y` is linear.

```
# Scatterplot of lstat vs. medv
plot(training_data$lstat, training_data$medv)
```

According to the plot, we see that the relationship is not linear. Let's try a transformation of our explanatory variable `lstat`.

```
# Scatterplot of log(lstat) vs. medv
plot(log(training_data$lstat), training_data$medv)
```

Look at the plot, it is more linear, so we can proceed and perform `lm()`:

STEP 3: Run the linear regression model

```
model = lm(medv ~ log(lstat), data = training_data)
model
#ans>
#ans> Call:
#ans> lm(formula = medv ~ log(lstat), data = training_data)
#ans>
#ans> Coefficients:
```

```
#ans> (Intercept)    log(lstat)
#ans>          51.8      -12.2
```

Notice that basic information when we print `model`. This only give us the slope (-12.2) and the intercept (51.8) of the linear model. Note that here we are looking at `log(lstat)` and not `lstat` anymore. So for every one unit increase in `lstat`, the median value of the house will decrease by $e^{12.2}$. For more detailed information, we can use the `summary()` function:

```
summary(model)
#ans>
#ans> Call:
#ans> lm(formula = medv ~ log(lstat), data = training_data)
#ans>
#ans> Residuals:
#ans>      Min       1Q   Median       3Q      Max
#ans> -11.385  -3.908  -0.779   2.245  25.728
#ans>
#ans> Coefficients:
#ans>              Estimate Std. Error t value Pr(>|t|)
#ans> (Intercept)    51.783      1.097    47.2  <2e-16 ***
#ans> log(lstat)   -12.203      0.472   -25.9  <2e-16 ***
#ans> ---
#ans> Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
#ans>
#ans> Residual standard error: 5.6 on 398 degrees of freedom
#ans> Multiple R-squared:  0.627,    Adjusted R-squared:  0.626
#ans> F-statistic: 669 on 1 and 398 DF,  p-value: <2e-16
```

Now, we have access to p-values and standard errors for the coefficients, as well as the R^2 .

- The output states that the slope is statistically significant and different from 0 and with a t-value = -25.9 (p-value < 0.05), which means that there is a significant relationship between the percentage of households with low socioeconomic income and the median house value.
- This relationship is negative. That is as the percentage of household with low socioeconomic income increases, the median house value decreases.
- Looking at R^2 , we can deduce that 62.7% of the model variation is being explained by the predictor `log(lstat)`. This is probably low, but indeed it would increase if we had more independent (explanatory) variables. We can use the `names()` function to see what other pieces of information are stored in our linear model (`model`).

```
names(model)
#ans> [1] "coefficients" "residuals"    "effects"      "rank"
#ans> [5] "fitted.values" "assign"        "qr"           "df.residual"
#ans> [9] "xlevels"      "call"          "terms"        "model"

model$coefficients
#ans> (Intercept)    log(lstat)
#ans>          51.8      -12.2
```

To obtain the confidence interval for the linear model (`model`), we can use the `confint()` function:

```
confint(model, level = 0.95)
#ans>           2.5 % 97.5 %
#ans> (Intercept)  49.6   53.9
#ans> log(lstat) -13.1  -11.3
```

So, a 95% confidence interval for the slope of `log(lstat)` is $(-13.13, -11.28)$. Notice that this confidence

interval gives us the same result as the hypothesis test performed earlier, by stating that we are 95% confident that the slope of `lstat` is not zero (in fact it is less than zero, which means that the relationship is negative.)

STEP 4: Plot the regression model

Now, let's plot our regression line on top of our data.

```
# Scatterplot of lstat vs. medv
plot(log(training_data$lstat), training_data$medv)

# Add the regression line to the existing scatterplot
abline(model)
```

Let's play with the look of the plot, and makes it prettier!

```
# Scatterplot of lstat vs. medv
plot(log(training_data$lstat), training_data$medv,
      xlab = "Log Transform of % of Houshold with Low Socioeconomic Income",
      ylab = "Median House Value",
      col = "red",
      pch = 20)

# Make the line color blue, and the line's width =3 (play with the width!)
abline(model, col = "blue", lwd =3)
```

STEP 5: Assess the model

Final thing we will do is to predict using our fitted model. We can use the `predict()` function for this purpose:

```
# Predict what is the median value of the house with lstat= 5%
predict(model, data.frame(lstat = c(5)))
#ans>      1
#ans> 32.1
```

```
# Predict what is the median values of houses with lstat= 5%, 10%, and 15%
predict(model, data.frame(lstat = c(5,10,15), interval = "prediction"))
#ans>      1      2      3
#ans> 32.1 23.7 18.7
```

Now let's assess our model, by computing the mean squared error (MSE). To assess the model we created, then we will be using the test data!

```
# Save the testing median values for houses (testing y) in y
y = testing_data$medv

# Compute the predicted value for this y (y hat)
y_hat = predict(model, data.frame(lstat = testing_data$lstat))

# Now we have both y and y_hat for our testing data.
# let's find the mean square error
error = y-y_hat
error_squared = error^2
MSE = mean(error_squared)
MSE
#ans> [1] 17.7
```

Chapter 2

Multiple Linear Regression

Simple linear regression is a useful approach for predicting a response on the basis of a single predictor variable. However, in practice we often have more than one predictor. In the previous chapter, we took for example the prediction of housing prices considering we had the size of each house. We had a single feature X , the size of the house. But now imagine if we had not only the size of the house as a feature but we also knew the number of bedrooms, the number of floors and the age of the house in years. It seems like this would give us a lot more information with which to predict the price.

2.1 The Model

In general, suppose that we have p distinct predictors. Then the multiple linear regression model takes the form

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p + \epsilon$$

where X_j represents the j th predictor and β_j quantifies the association between that variable and the response. We interpret β_j as the average effect on Y of a one unit increase in X_j , holding all other predictors fixed.

In matrix terms, supposing we have n observations and p variables, we need to define the following matrices:

$$\mathbf{Y}_{n \times 1} = \begin{pmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_n \end{pmatrix} \quad \mathbf{X}_{n \times (p+1)} = \begin{pmatrix} 1 & X_{11} & X_{12} & \cdots & X_{1p} \\ 1 & X_{21} & X_{22} & \cdots & X_{2p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & X_{n1} & X_{n2} & \cdots & X_{np} \end{pmatrix} \quad (2.1)$$

$$\beta_{(p+1) \times 1} = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_p \end{pmatrix} \quad \epsilon_{n \times 1} = \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_n \end{pmatrix} \quad (2.2)$$

In matrix terms, the general linear regression model is

$$\mathbf{Y}_{n \times 1} = \mathbf{X}_{n \times (p+1)} \beta_{(p+1) \times 1} + \epsilon_{n \times 1}$$

where,

- \mathbf{Y} is a vector of responses.
- β is a vector of parameters.
- \mathbf{X} is a matrix of constants.
- ϵ is a vector of independent normal (Gaussian) random variables.

2.2 Estimating the Regression Coefficients

As was the case in the simple linear regression setting, the regression coefficients $\beta_0, \beta_1, \dots, \beta_p$ are unknown, and must be estimated. Given estimates $\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_p$, we can make predictions using the formula

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x_1 + \hat{\beta}_2 x_2 + \dots + \hat{\beta}_p x_p$$

We choose $\beta_0, \beta_1, \dots, \beta_p$ to minimize the sum of squared residuals

$$\begin{aligned} RSS &= \sum_{i=1}^n (y_i - \hat{y}_i)^2 \\ &= \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 \hat{x}_{i1} - \hat{\beta}_2 \hat{x}_{i2} - \dots - \hat{\beta}_p \hat{x}_{ip})^2 \end{aligned}$$

The values $\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_p$ that minimize the RSS are the multiple least squares regression coefficient estimates, they are calculated using this formula (in matrix terms):

$$\hat{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y}$$

Note 1:

It is a remarkable property of matrix algebra that the results for the general linear regression model in matrix notation appear exactly as those for the simple linear regression model. Only the degrees of freedom and other constants related to the number of X variables and the dimensions of some matrices are different.

Note 2:

If $\mathbf{X}^T \mathbf{X}$ is noninvertible, the common causes might be having:

- Redundant features, where two features are very closely related (i.e. they are linearly dependent)
- Too many features (e.g. $p \geq n$). In this case, we delete some features or we use “regularization” (to be, maybe, explained in a later lesson).

2.3 Some important questions

When we perform multiple linear regression, we usually are interested in answering a few important questions.

1. Is at least one of the predictors X_1, X_2, \dots, X_p useful in predicting the response?
2. Do all the predictors help to explain Y , or is only a subset of the predictors useful?
3. How well does the model fit the data?

4. Given a set of predictor values, what response value should we predict, and how accurate is our prediction?

Relationship Between the Response and Predictors?

F-Statistic

Recall that in the simple linear regression setting, in order to determine whether there is a relationship between the response and the predictor we can simply check whether $\beta_1 = 0$. In the multiple regression setting with p predictors, we need to ask whether all of the regression coefficients are zero, i.e. whether $\beta_1 = \beta_2 = \dots = \beta_p = 0$. As in the simple linear regression setting, we use a hypothesis test to answer this question. We test the null hypothesis,

$$H_0 : \beta_1 = \beta_2 = \dots = \beta_p = 0$$

versus the alternative hypothesis

$$H_1 : \text{at least one } \beta_j \text{ is non-zero}$$

This hypothesis test is performed by computing the F -statistic (Fisher):

$$F = \frac{(\text{TSS} - \text{RSS})/p}{\text{RSS}/(n - p - 1)} \sim F_{p, n-p-1}$$

where, as with simple linear regression, $\text{TSS} = \sum (y_i - \bar{y})^2$ and $\text{RSS} = \sum (y_i - \hat{y}_i)^2$.

When the F -statistic value is close to 1, then H_0 is true, which means there is no relationship between the response and predictors. On the other hand, if H_1 is true, so we expect F to be greater than 1.

So the question we ask here: Is the whole regression explaining anything at all? The answer comes from the F -test in the ANOVA (ANalysis Of VAriance) table. This is what we get in an ANOVA table:

Source	df	SS	MS	F	p-value
Factor (Explained)	$p - 1$	SST	$\text{SST}/(k - 1)$	MST/MSE	p-value
Error (Unexplained)	$n - p$	SSE	$\text{SSE}/(n - k)$		
Total	$n - 1$	SS			

The ANOVA table has many pieces of information. What we care about is the F Ratio and the corresponding p-value. We compare the F Ratio with $F_{(p-1, n-p)}$ and a corresponding α value (error).

p-values

The p-values provide information about whether each individual predictor is related to the response, after adjusting for the other predictors. Let's look at the following table we obtain in general using a statistical software for example

	Coefficient	Std. error	t -statistic	p-value
Constant	2.939	0.3119	9.42	<0.0001
X_1	0.046	0.0014	32.81	<0.0001
X_2	0.189	0.0086	21.89	<0.0001
X_3	-0.001	0.0059	-0.18	0.8599

In this table we have the following model

$$Y = 2.939 + 0.046X_1 + 0.189X_2 - 0.001X_3$$

Note that for each individual predictor a t -statistic and a p -value were reported. These p -values indicate that X_1 and X_2 are related to Y , but that there is no evidence that X_3 is associated with Y , in the presence of these two.

Deciding on Important Variables

The most direct approach is called all subsets or best subsets regression: we compute the least squares fit for all possible subsets and then choose between them based on some criterion that balances training error with model size.

However we often can't examine all possible models, since they are 2^p of them; for example when $p = 40$ there are over a billion models! Instead we need an automated approach that searches through a subset of them. Here are two commonly use approaches:

Forward selection:

- Begin with the null model — a model that contains an intercept (constant) but no predictors.
- Fit p simple linear regressions and add to the null model the variable that results in the lowest RSS.
- Add to that model the variable that results in the lowest RSS amongst all two-variable models.
- Continue until some stopping rule is satisfied, for example when all remaining variables have a p -value above some threshold.

Backward selection:

- Start with all variables in the model.
- Remove the variable with the largest p -value — that is, the variable that is the least statistically significant.
- The new ($p-1$)-variable model is fit, and the variable with the largest p -value is removed.
- Continue until a stopping rule is reached. For instance, we may stop when all remaining variables have a significant p -value defined by some significance threshold.

There are more systematic criteria for choosing an “optimal” member in the path of models produced by forward or backward stepwise selection. These include Mallows's C_p , Akaike information criterion (AIC), Bayesian information criterion (BIC), adjusted R^2 and Cross-validation (CV).

Model Fit

Two of the most common numerical measures of model fit are the RSE and R^2 , the fraction of variance explained. These quantities are computed and interpreted in the same fashion as for simple linear regression. Recall that in simple regression, R^2 is the square of the correlation of the response and the variable. In multiple linear regression, it turns out that it equals $Cor(Y, \hat{Y})^2$, the square of the correlation between the response and the fitted linear model; in fact one property of the fitted linear model is that it maximizes this correlation among all possible linear models. An R^2 value close to 1 indicates that the model explains a large portion of the variance in the response variable.

In general RSE is defined as

$$\text{RSE} = \sqrt{\frac{1}{n - p - 1} \text{RSS}}$$

2.3.1 Other Considerations in Regression Model

Qualitative Predictors

- If we have a categorical (qualitative) variable (feature), how do we fit into a regression equation?
- For example, if X_1 is the gender (male or female).
- We can code, for example, male = 0 and female = 1.
- Suppose X_2 is a quantitative variable, the regression equation becomes:

$$Y_i \approx \beta_0 + \beta_1 X_1 + \beta_2 X_2 = \begin{cases} \beta_0 + \beta_2 X_2 & \text{if male} \\ \beta_0 + \beta_1 X_1 + \beta_2 X_2 & \text{if female} \end{cases}$$

- Another possible coding scheme is to let male = -1 and female = 1, the regression equation is then:

$$Y_i \approx \beta_0 + \beta_1 X_1 + \beta_2 X_2 = \begin{cases} \beta_0 - \beta_1 X_1 + \beta_2 X_2 & \text{if male} \\ \beta_0 + \beta_1 X_1 + \beta_2 X_2 & \text{if female} \end{cases}$$

Interaction Terms

- When the effect on Y of increasing X_1 depends on another X_2 .
- We may in this case try the model

$$Y_i = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1 X_2$$

- $X_1 X_2$ is the Interaction term.

PW 2

2.4 Reporting

Markdown

Markdown is a lightweight markup language with plain text formatting syntax designed so that it can be converted to HTML and many other formats (pdf, docx, etc..).

Click [here](#) to see an example of a markdown (.md) syntaxes and the result in HTML. The markdown syntaxes are on right and their HTML result is on left. You can modify the source text to see the result.

Extra: There is some markdown online editors you can use, like dillinger.io/. See the Markdown source file and the HTML preview. Play with the source text to see the result in the preview.

R Markdown

R Markdown is a variant of Markdown that has embedded R code chunks, to be used with the **knitr** package to make it **easy to create reproducible web-based reports**.

First, in **Rstudio** create a new **R Markdown** file. A default template will be opened. There is some R code in **R chunks**. Click on **knit**, save your file and see the produced output. The output is a html report containing the results of the R codes. If your file is named **report.Rmd**, your report is named **report.html**.

- Make sure to have the latest version of **Rstudio**.
- If you have problems creating a **R Markdown** file (problem in installing packages, etc..) close your **Rstudio** and reopen it with administrative tools and retry.
- If it doesn't work and in order to not lose more time, write your script in an **.R** file with your comments and submit it.

- Be ready to submit your report (your **.html** file) at the end of each class.
- Your report must be named:

YouLastName_YourFirstName_WeekNumber.html

You can find all the informations about R Markdown on this site: rmarkdown.rstudio.com.

You may also find the following resources helpful:

- The R Markdown Reference Guide
- The R Markdown Cheatsheet

The report to be submitted

In **Rstudio**, start by creating a R Markdown file. When you create it a default template will be opened with the following first lines:

```
---
title: "Untitled"
output: html_document
---
```

These lines are the YAML header in which you choose the settings of your report (title, author, date, appearance, etc..)

For your submitted report, use the following YAML header:

```
---
title: "Week 2"
subtitle: "Multiple Linear Regression"
author: LastName FirstName
date: "2017-03-14 22:16:38"
output:
  html_document:
    toc: true
    toc_depth: 2
    theme: flatly
---
```

In the core of your report:

- Put every exercise in a section, name the section **Exercise i** (i is the exercise's number).
- Paste the exercise content.
- Write the code of the exercise in R chunks.
- Run the chunk to make sure it works.
- If there is a need, explain the results.
- Click on **knit**

2.5 Multiple Linear Regression

Submit a report following the instructions above. In the first exercise you must continue the analysis of the Boston data set.

The exercises

Continue what we started last week with the Boston dataset which is part of the **MASS** package. Recall that this dataset records the median value of houses for 506 neighborhoods around Boston.

1. Load the Boston dataset from **MASS** package.
2. Split the dataset into training set and testing set. (keep all the variables of the Boston data set)
3. Check if there is a linear relationship between the variables **medv** and **age**. (use **cor()** function).
4. Plot **medv** in function of **age**.
5. Train a regression model using both **lstat** and **age** as predictors of median house value. (Remember that we transformed **lstat**, use the same transformation here). What is the obtained model?

6. Print the summary of the obtained regression model.
7. Are the predictors significant?
8. Is the model as a whole significant ?
9. Train a new model using all the variables of the dataset. (We can use `.` as a short cut instead of writing down all the variables names)
10. When using all the variables as predictors, we didn't transform `lstat`. Re train the model using `log(lstat)` instead of `lstat`.
11. Did R^2 improve ?
12. To see if there is correlated variables print the correlation matrix using the `cor()` function (round the correlations with 2 digits).
13. Visualize the correlations using the `corrplot` package. To do so, install the `corrplot` package, load it, then use the function `corrplot.mixed()`. See this link for examples and to understand how to use it.
14. What is the correlation between `tax` and `rad`?
15. Run the model again without `rad`. What happens to the R^2 ? and for the F-statistic?

Of course R^2 should go a little lower because we deleted one of the variables. But check for the model significance (F-statistic) gets higher, which means the p-values gets lower and thus the model is more significant without `rad`.

16. Calculate the mean squared error (MSE) for the last model.

ANOVA

17. In the Boston data set there is a categorical variable `chas` which corresponds to Charles River (= 1 if a suburb bounds the river; 0 otherwise). How many of the suburbs in this data set bound the Charles river?
18. Create Boxplots of the median value of houses with respect to the variable `chas`. Do we observe some difference between the median value of houses with respect to the neighborhood to Charles River?
19. Next we will apply an analysis of variances (ANOVA) in order to test if there is a significant difference of means between two groups i and j (Consider group i is the suburbs bounding the river and j the suburbs which not). The hypotheses are

$$H_0 : \mu_i = \mu_j$$

$$H_1 : \mu_i \neq \mu_j$$

Where μ_i is the mean of `medv` in group i .

Calculate μ_i and μ_j (in one line using the function `aggregate()`).

20. Apply an ANOVA test of `medv` with respect to `chas` (use the function `aov()`). Print the result and the summary of it. what do you conclude ?

Part III

Classification

Chapter 3

Logistic Regression

3.1 Introduction

In the previous chapters we discussed the linear regression model, which assumes that the response variable Y is quantitative. But in many situations, the response variable is instead qualitative (categorical). For example, eye color is qualitative, taking on values blue, brown, or green.

The process for predicting qualitative responses is known as *classification*.

Given a feature vector X and a qualitative response Y taking values in the set \mathcal{C} , the classification task is to build a function $C(X)$ that takes as input the feature vector X and predicts its value for Y ; i.e. $C(X) \in \mathcal{C}$. We are often more interested in estimating the probabilities that X belongs to each category in \mathcal{C} .

If c is a category ($c \in \mathcal{C}$), by the probability that X belongs to c we mean $p(X \in c) = \mathbb{P}(Y = c|X)$.

In the binomial or binary logistic regression, the outcome can have only two possible types of values (e.g. “Yes” or “No”, “Success” or “Failure”). Multinomial logistic refers to cases where the outcome can have three or more possible types of values (e.g., “good” vs. “very good” vs. “best”). Generally outcome is coded as “0” and “1” in binary logistic regression.

3.2 Logistic Regression

Consider a data set where the response falls into one of two categories, Yes or No. Rather than modeling the response Y directly, logistic regression models the probability that Y belongs to a particular category.

3.2.1 The Logistic Model

Let us suppose the response has two categories and we use the generic 0/1 coding for the response. How should we model the relationship between $p(X) = \mathbb{P}(Y = 1|X)$ and X ?

The simplest situation is when Y is binary: it can only take two values, codified for convenience as 0 (success) and 1 (failure).

More formally, a binary variable is known as a Bernoulli variable, which is the simplest non-trivial random variable. We say that $Y \sim \text{Ber}(p)$, $0 \leq p \leq 1$, if

$$Y = \begin{cases} 1, & \text{with probability } p, \\ 0, & \text{with probability } 1 - p, \end{cases}$$

or, equivalently, if $\mathbb{P}[Y = 1] = p$ and $\mathbb{P}[Y = 0] = 1 - p$, which can be written compactly as

$$\mathbb{P}[Y = y] = p^y(1 - p)^{1-y}, \quad y = 0, 1.$$

Recall that a binomial variable with size n and probability p , $\text{Bi}(n, p)$, was obtained by adding n independent $\text{Ber}(p)$ (so $\text{Ber}(p)$ is the same as $\text{Bi}(1, p)$).

A Bernoulli variable Y is completely determined by p . **So its mean and variance:**

- $\mathbb{E}[Y] = p \times 1 + (1 - p) \times 0 = p$
- $\mathbb{V}\text{ar}[Y] = p(1 - p)$.

In particular, recall that $\mathbb{P}[Y = 1] = \mathbb{E}[Y] = p$.

Assume then that Y is a binary/Bernoulli variable and that X are predictors associated to them (no particular assumptions on them). The purpose in logistic regression is to estimate

$$p(x) = \mathbb{P}[Y = 1|X = x] = \mathbb{E}[Y|X = x],$$

this is, how the probability of $Y = 1$ is changing according to particular values, denoted by x , of the random variables X .

Why not linear regression? A tempting possibility is to consider the model

$$p(x) = \beta_0 + \beta_1 x.$$

However, such a model will run into problems inevitably: negative probabilities and probabilities larger than one ($p(x) < 0$ for some values of X and $p(X) > 1$ for others). To avoid this problem, the solution is to consider a function to encapsulate the value of $z = \beta_0 + \beta_1 x$, in \mathbb{R} , and map it to $[0, 1]$. There are several alternatives to do so, based on distribution functions $F : \mathbb{R} \rightarrow [0, 1]$ that deliver $y = F(z) \in [0, 1]$. Many functions meet this description. In logistic regression, we use the logistic function,

$$p(X) = \frac{e^{\beta_0 + \beta_1 X}}{1 + e^{\beta_0 + \beta_1 X}}$$

- No matter what values β_0 , β_1 or X take, $p(X)$ will have values between 0 and 1.
- The logistic function will always produce an S-shaped curve.
- The logistic distribution function is:

$$F(z) = \text{logistic}(z) = \frac{e^z}{1 + e^z} = \frac{1}{1 + e^{-z}}.$$

After a bit of manipulation of the previous equation, we find that

$$\frac{p(X)}{1 - p(X)} = e^{\beta_0 + \beta_1 X}$$

The quantity $p(X)/[1 - p(X)]$ is called the odds, and can take on any value between 0 and ∞ .

By taking the logarithm of both sides of the equation, we arrive at

$$\log\left(\frac{p(X)}{1 - p(X)}\right) = \beta_0 + \beta_1 X$$

The left-hand side is called the log-odds or logit. We see that the logistic regression model has a logit that is linear in X .

3.2.2 Estimating the Regression Coefficients

We estimate β_0 and β_1 using the Maximum Likelihood Estimation method (MLE). The basic intuition behind using maximum likelihood to fit a logistic regression model is as follows: we seek estimates for β_0 and β_1 such that the predicted probability $\hat{p}(x_i)$ of the response for each individual, corresponds as closely as possible to the individual's observed response status (recall that the response Y is categorical). The likelihood function is

$$l(\beta_0, \beta_1) = \prod_{i=1}^n p(x_i)^{Y_i} (1 - p(x_i))^{1-Y_i}.$$

This likelihood is **the probability of the data based on the model**. It gives the probability of the observed zeros and ones in the data. The estimates $\hat{\beta}_0$ and $\hat{\beta}_1$ are chosen to maximize this likelihood function. The interpretation of the likelihood function is the following:

- $\prod_{i=1}^n$ appears because the sample elements are assumed to be independent and we are computing the probability of observing the whole sample $(x_1, y_1), \dots, (x_n, y_n)$. This probability is equal to the product of the probabilities of observing each (x_i, y_i) .
- $p(x_i)^{Y_i} (1 - p(x_i))^{1-Y_i}$ is the probability of observing (x_i, Y_i) .

In the linear regression setting, the least squares approach is a special case of maximum likelihood.

We will not give mathematical details about the maximum likelihood and how to estimate the parameters. We will use R to fit the logistic regression models (using `glm` function).

Click here to see how the log-likelihood changes with respect to the values for (β_0, β_1) in three data patterns. The logistic regression fit and its dependence on β_0 (horizontal displacement) and β_1 (steepness of the curve). Recall the effect of the sign of β_1 in the curve: if positive, the logistic curve has an *s* form; if negative, the form is a reflected *s*.

3.2.3 Prediction

Example

	Coefficient	Std. error	Z-statistic	p-value
Constant	-10.6513	0.3612	-29.5	<0.0001
X	0.0055	0.0002	24.9	<0.0001

In this example, $\hat{\beta}_0 = -10.6513$ and $\hat{\beta}_1 = 0.0055$. It produces the blue curve that separates that data in the following figure,

Figure 3.1:

As for prediction, we use the model built with the estimated parameters to predict probabilities. For example, If $X = 1000$,

$$\hat{p}(X) = \frac{e^{\hat{\beta}_0 + \hat{\beta}_1 X}}{1 + e^{\hat{\beta}_0 + \hat{\beta}_1 X}} = \frac{e^{-10.6513 + 0.0055 \times 1000}}{1 + e^{-10.6513 + 0.0055 \times 1000}} = 0.006$$

If $X = 2000$,

$$\hat{p}(X) = \frac{e^{\hat{\beta}_0 + \hat{\beta}_1 X}}{1 + e^{\hat{\beta}_0 + \hat{\beta}_1 X}} = \frac{e^{-10.6513 + 0.0055 \times 2000}}{1 + e^{-10.6513 + 0.0055 \times 2000}} = 0.586$$

3.3 Multiple Logistic Regression

We now consider the problem of predicting a binary response using multiple predictors. By analogy with the extension from simple to multiple linear regression in the previous chapters, we can generalize the simple logistic regression equation as follows:

$$\log\left(\frac{p(X)}{1-p(X)}\right) = \beta_0 + \beta_1 X_1 + \dots + \beta_p X_p$$

where $X = (X_1, \dots, X_p)$ are p predictors. The equation above can be rewritten as

$$p(X) = \frac{e^{\beta_0 + \beta_1 X_1 + \dots + \beta_p X_p}}{1 + e^{\beta_0 + \beta_1 X_1 + \dots + \beta_p X_p}}$$

Just as in the simple logistic regression we use the maximum likelihood method to estimate $\beta_0, \beta_1, \dots, \beta_p$.

Name the file `LastName_FirstName_Week3` and submit the html output.

Social Networks Ads

In this PW we are going to analyse the `Social_Network_Ads` dataset. This dataset contains informations of users of a social network. The social network has several business clients and its business clients put ads on the social network for marketing campaigns purposes. For this dataset, a company has put ads for one of its new products and the social network gathered some informations about wich users responded positively to the ad by buying the product and those who responded negatively by not buying the product.

1. Download the `Social_Network_Ads` dataset from here and import it into R.
2. Describe the dataset (you can use `str()` and `summary()` functions).

We will consider the variables `Age` and `EstimatedSalary` as input variables (features) to see the correlations between them and the decision of the user to buy (or not) the product.

3. Now we are going to split the dataset into training set and test set. Last week we did it manually. From now on we will split it randomly with this code,

```
library(caTools) # install it first in the console
set.seed(123)
# we use this function with the same number
# to randomly generate the same values
split = sample.split(dataset$Purchased, SplitRatio = 0.75)
```

```
# here we chose the SplitRatio to 75% of the dataset,
# and 25% for the test set.
training_set = subset(dataset, split == TRUE)
# we use subset to split the dataset
test_set = subset(dataset, split == FALSE)
```

4. Scale the input variables in both training set and test set.

First let us fit a simple logistic regression model of `Purchased` in function of `Age`. We do it with this line of code,

```
classifier <- glm(Purchased ~ Age , family = binomial, data=training_set)
# glm goes for generalized linear model
```

5. In the argument `family` of the function `glm` we chose `binomial`. Why ?
6. What is the equation of the obtained model in the question 4 ?
7. Is the feature `Age` significant?

The **AIC** is the **Akaike Information Criterion**. You will use this while comparing multiple models. The model with lower value of AIC is better. Suppose that we have a statistical model of some data. Let \hat{L} be the maximum value of the likelihood function for the model; let k be the number of estimated parameters in the model. Then the AIC value of the model is the following.

$$\text{AIC} = 2k - 2 \ln(\hat{L})$$

where

- \hat{L} = the maximized value of the likelihood function of the model M , i.e. $\hat{L} = p(x|\hat{\beta}, M)$, where $\hat{\beta}$ are the parameter values that maximize the likelihood function.
- x = the observed data.
- k = the number of free parameters to be estimated. If the model under consideration is a linear regression, k is the number of regressors, including the intercept.

8. Plot `Purchased` in function of `Age` and add the curve of the obtained logistic regression model.

(**Hints:** First plot the point, then use the `curve()` function with option `add=TRUE` to add the curve to the plot. The argument “type” of the function `predict()` must be “reponse”)

You must obtain something like

Figure 3.2:

Extra: A great R package for visualization is `ggplot2`. Take a look on this link for some examples. With this library we obtain the following plot for our model,

Figure 3.3:

I obtained the last figure with these lines of code,

```
library(ggplot2)
ggplot(training_set, aes(x=Age, y=Purchased)) +
  geom_point() +
  stat_smooth(method="glm", method.args=list(family="binomial"), se=FALSE)
```

9. Now let us take another feature into account in the model. Fit a logistic regression model of purchasing

the product in function of the age of the user and its salary.

10. Are the predictors significant? Did the model get better by adding the estimated salary?
11. On the test set, predict the probability of purchasing the product by the users using the obtained model.
12. Take a look on your predicted values for the variable **Purchased**. We predicted the probability that the user will purchase the product right? Now in order to compare your results with the real answers, transform the predicted values to 0 or 1 (1 if >0.5).

Hint: You can easily do it with the `ifelse()` function.

Now read the following about the evaluation of a classifier (of a classification model).

Confusion matrix: is a tabular representation of Actual vs Predicted values. This helps us to find the accuracy of the model. The different results from a binary classifier are true positives, true negatives, false positives, and false negatives. This is how the confusion matrix looks like:

		True condition			
		Total population	Condition positive	Condition negative	Prevalence $= \frac{\Sigma \text{Condition positive}}{\Sigma \text{Total population}}$
Predicted condition	Predicted condition positive	True positive	False positive (Type I error)	Positive predictive value (PPV), Precision $= \frac{\Sigma \text{True positive}}{\Sigma \text{Test outcome positive}}$	False discovery rate (FDR) = $\frac{\Sigma \text{False positive}}{\Sigma \text{Test outcome positive}}$
	Predicted condition negative	False negative (Type II error)	True negative	False omission rate (FOR) $= \frac{\Sigma \text{False negative}}{\Sigma \text{Test outcome negative}}$	Negative predictive value (NPV) $= \frac{\Sigma \text{True negative}}{\Sigma \text{Test outcome negative}}$
		Accuracy (ACC) = $\frac{\Sigma \text{True positive} + \Sigma \text{True negative}}{\Sigma \text{Total population}}$	True positive rate (TPR), Sensitivity, Recall $= \frac{\Sigma \text{True positive}}{\Sigma \text{Condition positive}}$ False negative rate (FNR), Miss rate $= \frac{\Sigma \text{False negative}}{\Sigma \text{Condition positive}}$	False positive rate (FPR), Fall-out $= \frac{\Sigma \text{False positive}}{\Sigma \text{Condition negative}}$ True negative rate (TNR), Specificity (SPC) $= \frac{\Sigma \text{True negative}}{\Sigma \text{Condition negative}}$	Positive likelihood ratio (LR+) $= \frac{\text{TPR}}{\text{FPR}}$ Negative likelihood ratio (LR-) $= \frac{\text{FNR}}{\text{TNR}}$ Diagnostic odds ratio (DOR) $= \frac{\text{LR+}}{\text{LR-}}$

(Image source: Wikipedia)

You can calculate the **accuracy** of your model with:

$$\frac{\text{True Positive} + \text{True Negatives}}{\text{True Positive} + \text{True Negatives} + \text{False Positives} + \text{False Negatives}}$$

Figure 3.4:

Accuracy is a key measure of performance, and is more specifically the rate at which the model is able to predict the correct value (classification or regression) for a given data point or observation. In other words, accuracy is the proportion of correct predictions out of all predictions made.

The other two metrics from the confusion matrix worth discussing are **precision** and **recall**. Precision (positive predictive value) is the ratio of true positives to the total amount of positive predictions made (i.e., true or false). Said another way, precision measures the proportion of accurate positive predictions out of all positive predictions made.

Recall on the other hand, or true positive rate, is the ratio of true positives to the total amount of actual positives, whether predicted correctly or not. So in other words, recall measures the proportion of accurate positive predictions out of all actual positive observations.

A metric that is associated with precision and recall is called the F-score (also called F1 score), which combines them mathematically, and somewhat like a weighted average, in order to produce a single measure of performance based on the simultaneous values of both. Its values range from 0 (worst) to 1 (best).

Another important concept to know about is the *Receiver Operating Characteristic*, which when plotted, results in what's known as an ROC curve.

ROC Curve: An ROC curve is a two-dimensional plot of sensitivity (recall, or true positive rate) vs specificity (false positive rate). The area under the curve is referred to as the *AUC*, and is a numeric metric used to represent the quality and performance of the classifier (model).

Figure 3.5:

An AUC of 0.5 is essentially the same as random guessing without a model, whereas an AUC of 1.0 is considered a perfect classifier. Generally, the higher the AUC value the better, and an AUC above 0.8 is considered quite good.

The higher the AUC value, the closer the curve gets to the upper left corner of the plot. One can easily see from the ROC curves then that the goal is to find and tune a model that maximizes the true positive rate, while simultaneously minimizing the false positive rate. Said another way, the goal as shown by the ROC curve is to correctly predict as many of the actual positives as possible, while also predicting as many of the actual negatives as possible, and therefore minimize errors (incorrect classifications) for both.

13. Now to evaluate the predictions, compute the confusion matrix. What do you obtain ?

(**Hint:** you can use the `table()` function).

14. Calculate the accuracy, specificity, sensitivity and the precision of the model.
15. Plot the ROC curve and calculate AUC value.

Hints: to plot it, install the `ROCR` package. Load and use the functions:

- `prediction()` to calculate the elements of the confusion matrix.
- `performance()` to calculate the AUC.
- `plot()` to plot the ROC curve, you can plot the performance calculated before.
- `abline()` to plot a line of equation $y=x$.

16. Compare the AUC of the two models you fitted (one with only age and one with age and estimated salary) and plot their ROC curves in the same figure.

Chapter 4

Linear Discriminant Analysis

Discriminant analysis is a popular method for multiple-class classification. We will start first by the Linear Discriminant Analysis (LDA).

4.1 Introduction

As we saw in the previous chapter, Logistic regression involves directly modeling $\mathbb{P}(Y = k|X = x)$ using the logistic function, for the case of two response classes. In logistic regression, we model the conditional distribution of the response Y , given the predictor(s) X . We now consider an alternative and less direct approach to estimating these probabilities. In this alternative approach, ***we model the distribution*** of the predictors X ***separately*** in each of the response classes (i.e. given Y), and then use **Bayes' theorem** to flip these around into estimates for $\mathbb{P}(Y = k|X = x)$. When these distributions are assumed to be Normal, it turns out that the model is very similar in form to logistic regression.

Why not logistic regression? Why do we need another method, when we have logistic regression? There are several reasons:

- When the classes are well-separated, the parameter estimates for the logistic regression model are surprisingly unstable. Linear discriminant analysis does not suffer from this problem.
- If n is small and the distribution of the predictors X is approximately normal in each of the classes, the linear discriminant model is again more stable than the logistic regression model.
- Linear discriminant analysis is popular when we have more than two response classes.

4.2 Bayes' Theorem

Bayes' theorem is stated mathematically as the following equation:

$$P(A|B) = \frac{P(A \cap B)}{P(B)} = \frac{P(B|A)P(A)}{P(B)}$$

where A and B are events and $P(B) \neq 0$.

- $P(A|B)$, a conditional probability, is the probability of observing event A given that B is true. It is called the ***posterior*** probability.
- $P(A)$, is called the ***prior***, is the initial degree of belief in A .
- $P(B)$ is the ***likelihood***.

The posterior probability can be written in the memorable form as :

Posterior probability \propto Likelihood \times Prior probability.

Extended form:

Suppose we have a partition $\{A_i\}$ of the sample space, the even space is given or conceptualized in terms of $P(A_j)$ and $P(B|A_j)$. It is then useful to compute $P(B)$ using the law of total probability:

$$P(B) = \sum_j P(B|A_j)P(A_j)$$

$$\Rightarrow P(A_i|B) = \frac{P(B|A_i)P(A_i)}{\sum_j P(B|A_j)P(A_j)}$$

Bayes' Theorem for Classification:

Suppose that we wish to classify an observation into one of K classes, where $K \geq 2$. In other words, the qualitative response variable Y can take on K possible distinct and unordered values.

Let π_k represent the overall or prior probability that a randomly chosen observation comes from the k -th class; this is the probability that a given observation is associated with the k -th category of the response variable Y .

Let $f_k(X) \equiv P(X = x|Y = k)$ denote the density function of X for an observation that comes from the k -th class. In other words, $f_k(x)$ is relatively large if there is a high probability that an observation in the k -th class has $X \approx x$, and $f_k(x)$ is small if it is very unlikely that an observation in the k -th class has $X \approx x$. Then Bayes' theorem states that

$$P(Y = k|X = x) = \frac{\pi_k f_k(x)}{\sum_{c=1}^K \pi_c f_c(x)} \quad (4.1)$$

As we did in the last chapter, we will use the abbreviation $p_k(X) = P(Y = k|X)$.

The equation above stated by Bayes' theorem suggests that instead of directly computing $p_k(X)$ as we did in the logistic regression, we can simply plug in estimates of π_k and $f_k(X)$ into the equation. In general, estimating π_k is easy (the fraction of the training observations that belong to the k -th class). But estimating $f_k(X)$ tends to be more challenging.

Recall that $p_k(x)$ is the posterior probability that an observation $X = x$ belongs to k -th class.

If we can find a way to estimate $f_k(X)$, we can develop a classifier with the lowest possible error rate out of all classifiers.

4.3 LDA for $p = 1$

Assume that $p = 1$, which mean we have only one predictor. We would like to obtain an estimate for $f_k(x)$ that we can plug into the Equation (4.1) in order to estimate $p_k(x)$. **We will then classify an observation to the class for which $p_k(x)$ is greatest.**

In order to estimate $f_k(x)$, we will first make some assumptions about its form.

Suppose we assume that $f_k(x)$ is normal (Gaussian). In the one-dimensional setting, the normal density take the form

$$f_k(x) = \frac{1}{\sigma_k \sqrt{2\pi}} \exp\left(-\frac{1}{2\sigma_k^2}(x - \mu_k)^2\right) \quad (4.2)$$

where μ_k and σ_k^2 are the mean and variance parameters for k -th class. Let us assume that $\sigma_1^2 = \dots = \sigma_K^2 = \sigma^2$ (which means there is a shared variance term across all K classes). Plugging Eq. (4.2) into the Bayes formula in Eq. (4.1) we get,

$$p_k(x) = \frac{\pi_k \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu_k}{\sigma}\right)^2}}{\sum_{c=1}^K \pi_c \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu_c}{\sigma}\right)^2}} \quad (4.3)$$

Note that π_k and π_c denote the prior probabilities. And π is the mathematical constant $\pi \approx 3.14159$.

To classify at the value $X = x$, we need to see which of the $p_k(x)$ is largest. Taking logs, and discarding terms that do not depend on k , we see that this is equivalent to assigning x to the class with the largest **discriminant score**:

$$\delta_k(x) = x \cdot \frac{\mu_k}{\sigma^2} - \frac{\mu_k^2}{2\sigma^2} + \log(\pi_k) \quad (4.4)$$

Note that $\delta_k(x)$ is a linear function of x .

- The decision surfaces for a linear discriminant classifiers are defined by the linear equations $\delta_k(x) = \delta_c(x)$.
- Example: If $K = 2$ and $\pi_1 = \pi_2$, then the **decision boundary** is at $x = \frac{\mu_1 + \mu_2}{2}$ (**Prove it!**).
- An example where $\mu_1 = -1.5$, $\mu_2 = 1.5$, $\mu_1 = \mu_2 = 0.5$ and $\sigma^2 = 1$ is shown in this following figure

- See this video to understand more about decision boundary.
- As we classify a new point according to which density is highest, when the priors are different we take them into account as well, and compare $\pi_k f_k(x)$. On the right of the following figure, we favor the pink class (remark that the decision boundary has shifted to the left).

4.4 Estimating the parameters

Typically we don't know these parameters; we just have the training data. In that case we simply estimate the parameters and plug them into the rule.

Let n the total number of training observations, and n_k the number of training observations in the k -th class. The following estimates are used:

$$\begin{aligned}\hat{\pi}_k &= \frac{n_k}{n} \\ \hat{\mu}_k &= \frac{1}{n_k} \sum_{i:y_i=k} x_i \\ \hat{\sigma}^2 &= \frac{1}{n-K} \sum_{k=1}^K \sum_{i:y_i=k} (x_i - \hat{\mu}_k)^2 \\ &= \sum_{k=1}^K \frac{n_k - 1}{n - K} \cdot \hat{\sigma}_k^2\end{aligned}$$

where $\hat{\sigma}_k^2 = \frac{1}{n_k - 1} \sum_{i:y_i=k} (x_i - \hat{\mu}_k)^2$ is the usual formula for the estimated variance in the k -th class.

The linear discriminant analysis (LDA) classifier plugs these estimates in Eq. (4.4) and assigns an observation $X = x$ to the class for which

$$\hat{\delta}_k(x) = x \cdot \frac{\hat{\mu}_k}{\hat{\sigma}^2} - \frac{\hat{\mu}_k^2}{2\hat{\sigma}^2} + \log(\hat{\pi}_k) \quad (4.5)$$

is largest.

The discriminant functions in Eq. (4.5) are linear functions of x .

Recall that we assumed that the observations come from a normal distribution with a common variance σ^2 .

4.5 LDA for $p > 1$

Let us now suppose that we have multiple predictors. We assume that $X = (X_1, X_2, \dots, X_p)$ is drawn from multivariate Gaussian distribution (assuming they have a common covariance matrix, e.g. same variances as in the case of $p = 1$). The multivariate Gaussian distribution assumes that each individual predictor follows a one-dimensional normal distribution as in Eq. (4.2), with some correlation between each pair of predictors.

To indicate that a p -dimensional random variable X has a multivariate Gaussian distribution, we write $X \sim \mathcal{N}(\mu, \Sigma)$. Where

$$\mu = E(X) = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_p \end{pmatrix}$$

and,

$$\Sigma = Cov(X) = \begin{pmatrix} \sigma_1^2 & Cov[X_1, X_2] & \dots & Cov[X_1, X_p] \\ Cov[X_2, X_1] & \sigma_2^2 & \dots & Cov[X_2, X_p] \\ \vdots & \vdots & \ddots & \vdots \\ Cov[X_p, X_1] & Cov[X_p, X_2] & \dots & \sigma_p^2 \end{pmatrix}$$

Σ is the $p \times p$ covariance matrix of X .

Formally, the multivariate Gaussian density is defined as

$$f(x) = \frac{1}{(2\pi)^{p/2} |\Sigma|^{1/2}} \exp \left(-\frac{1}{2} (x - \mu)^T \Sigma^{-1} (x - \mu) \right)$$

Plugging the density function for the k -th class, $f_k(X = x)$, into Eq. (4.1) reveals that the Bayes classifier assigns an observation $X = x$ to the class for which

$$\delta_k(x) = x^T \Sigma^{-1} \mu_k - \frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k + \log \pi_k \quad (4.6)$$

is largest. This is the vector/matrix version of (4.4).

An example is shown in the following figure. Three equally-sized Gaussian classes are shown with class-specific mean vectors and a common covariance matrix ($\pi_1 = \pi_2 = \pi_3 = 1/3$). The three ellipses represent regions that contain 95% of the probability for each of the three classes. The dashed lines are the Bayes decision boundaries.

Recall that the decision boundaries represent the set of values x for which $\delta_k(x) = \delta_c(x)$; i.e. for $k \neq c$

$$x^T \Sigma^{-1} \mu_k - \frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k = x^T \Sigma^{-1} \mu_c - \frac{1}{2} \mu_c^T \Sigma^{-1} \mu_c$$

Note that there are three lines representing the Bayes decision boundaries because there are three pairs of classes among the three classes. That is, one Bayes decision boundary separates class 1 from class 2, one separates class 1 from class 3, and one separates class 2 from class 3. These three Bayes decision boundaries divide the predictor space into three regions. The Bayes classifier will classify an observation according to the region in which it is located.

Once again, we need to estimate the unknown parameters μ_1, \dots, μ_k , and π_1, \dots, π_k , and Σ ; the formulas are similar to those used in the one-dimensional case. To assign a new observation $X = x$, LDA plugs these estimates into Eq. (4.6) and classifies to the class for which $\delta_k(x)$ is largest.

Note that in Eq. (4.6) $\delta_k(x)$ is a linear function of x ; that is, the LDA decision rule depends on x only through a linear combination of its elements. This is the reason for the word linear in LDA.

4.6 Making predictions

Once we have estimates $\hat{\delta}_k(x)$, we can turn these into estimates for class probabilities:

$$\hat{P}(Y = k | X = x) = \frac{e^{\hat{\delta}_k(x)}}{\sum_{c=1}^K e^{\hat{\delta}_c(x)}}$$

So classifying to the largest $\hat{\delta}_k(x)$ amounts to classifying to the class for which $\hat{P}(Y = k | X = x)$ is largest.

When $K = 2$, we classify to class 2 if $\hat{P}(Y = 2 | X = x) \geq 0.5$, else to class 1.

4.7 Other forms of Discriminant Analysis

$$P(Y = k | X = x) = \frac{\pi_k f_k(x)}{\sum_{c=1}^K \pi_c f_c(x)}$$

We saw before that when $f_k(x)$ are Gaussian densities, with the same covariance matrix Σ in each class, this leads to Linear Discriminant Analysis (LDA).

By altering the forms for $f_k(x)$, we get different classifiers.

- With Gaussians but different Σ_k in each class, we get Quadratic Discriminant Analysis (QDA).
- With $f_k(x) = \prod_{j=1}^p f_{jk}(x_j)$ (conditional independence model) in each class we get Naive Bayes. (For Gaussian, this mean the Σ_k are diagonal, e.g. $Cov(X_i, X_j) = 0 \forall 1 \leq i, j \leq p$).
- Many other forms by proposing specific density models for $f_k(x)$, including nonparametric approaches.

4.7.1 Quadratic Discriminant Analysis (QDA)

Like LDA, the QDA classifier results from assuming that the observations from each class are drawn from a Gaussian distribution, and plugging estimates for the parameters into Bayes' theorem in order to perform prediction.

However, unlike LDA, QDA assumes that each class has its own covariance matrix. Under this assumption, the Bayes classifier assigns an observation $X = x$ to the class for which

$$\begin{aligned}\delta_k(x) &= -\frac{1}{2}(x - \mu)^T \Sigma_k^{-1}(x - \mu) - \frac{1}{2} \log |\Sigma_k| + \log \pi_k \\ &= -\frac{1}{2}x^T \Sigma_k^{-1}x + \frac{1}{2}x^T \Sigma_k^{-1}\mu_k - \frac{1}{2}\mu_k^T \Sigma_k^{-1}\mu_k - \frac{1}{2} \log |\Sigma_k| + \log \pi_k\end{aligned}$$

is largest.

Unlike in LDA, the quantity x appears as a quadratic function in QDA. This is where QDA gets its name.

The decision boundary in QDA is non-linear. It is quadratic (a curve).

4.7.2 Naive Bayes

We use Naive Bayes classifier if the features are independant in each class. It is useful when p is large (unklike LDA and QDA).

Naive Bayes assumes that each Σ_k is diagonal, so

$$\begin{aligned}\delta_k(x) &\propto \log \left[\pi_k \prod_{j=1}^p f_{kj}(x_j) \right] \\ &= -\frac{1}{2} \sum_{j=1}^p \frac{(x_j - \mu_{kj})^2}{\sigma_{kj}^2} + \log \pi_k\end{aligned}$$

It can used for mixed feature vectors (qualitative and quantitative). If X_j is qualitative, we replace $f_{kj}(x_j)$ by probability mass function (histogram) over discrete categories.

4.8 LDA vs Logistic Regression

the logistic regression and LDA methods are closely connected. Consider the two-class setting with $p = 1$ predictor, and let $p_1(x)$ and $p_2(x) = 1 - p_1(x)$ be the probabilities that the observation $X = x$ belongs to class

1 and class 2, respectively. In the LDA framework, we can see from Eq. (4.4) (and a bit of simple algebra) that the log odds is given by

$$\log \left(\frac{p_1(x)}{1 - p_1(x)} \right) = \log \left(\frac{p_1(x)}{p_2(x)} \right) = c_0 + c_1 x$$

where c_0 and c_1 are functions of μ_1, μ_2 , and σ^2 .

On the other hand, we know that in logistic regression

$$\log \left(\frac{p_1}{1 - p_1} \right) = \beta_0 + \beta_1 x$$

Both of the equations above are linear functions of x . Hence both logistic regression and LDA produce linear decision boundaries. The only difference between the two approaches lies in the fact that β_0 and β_1 are estimated using maximum likelihood, whereas c_0 and c_1 are computed using the estimated mean and variance from a normal distribution. This same connection between LDA and logistic regression also holds for multidimensional data with $p > 1$.

- Logistic regression uses the conditional likelihood based on $P(Y|X)$ (known as discriminative learning).
- LDA uses the full likelihood based on $P(X, Y)$ (known as generative learning).
- Despite these differences, in practice the results are often very similar.

Remark: Logistic regression can also

fit quadratic boundaries like QDA, by explicitly including quadratic terms in the model.

PW 4

This week we are going to continue the analysis of the **Social_Network_Ads** dataset. Recall that this dataset contains informations of users of a social network and if they bought a specified product. Last week we built a Logistic Regression model for the variable **Purchased** in function of **Age** and **EstimatedSalary**. We will consider the same variables this week but we will fit different models using methods such as LDA, QDA, and Naive Bayes.

Report template

For this week, use these YAML settings for your RMarkdown file:

Decision Boundary of Logistic Regression

1. First, re-do the pre-processing steps you did last week (remove the first two columns from the dataset as we are not going to use them) and fit a logistic regression model of **Purchased** in function of **Age** and **EstimatedSalary**. Name your model `classifier.logreg`. If you need the dataset again, you can download it from [here](#).

Now you are going to visualize the decision boundary for logistic regression.

- Since the decision boundary of logistic regression is a linear (you know why right?) and the dimension of the feature space is 2 (**Age** and **EstimatedSalary**), the decision boundary in this 2-dimensional space is a line that separates the predicted classes “0” and “1” (values of the response **Purchased**).
- For logistic regression, we predict $y = 1$ if $\beta^T X \geq 0$ (right side of the line) and $y = 0$ if $\beta^T X < 0$ (left side of the line). Where

$$\beta = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \end{pmatrix} \text{ and } X = \begin{pmatrix} 1 \\ X_1 \\ X_2 \end{pmatrix}$$

So we predict $y = 1$ if $\beta_0 + \beta_1 X_1 + \beta_2 X_2 \geq 0$ which means that the equation of the decision boundary (a line here) is $X_2 = -\frac{\beta_1}{\beta_2} X_1 - \frac{\beta_0}{\beta_2}$

2. Plot the decision boundary obtained with logistic regression. In order to do so, calculate the intercept and the slope of the line presenting the decision boundary, then plot `EstimatedSalary` in function of `Age` (from the `test_set`) and add the line using `abline()`.

3. In order to verify that your line (decision boundary) is well plotted, color the points on the last Figure with respect to the predicted response.

Hints:

- If your predictions are stored in `y_pred`, you can do it using `bg = ifelse(y_pred == 1, 'color1', 'color2')`, and precise the argument `pch` to be 21 (you can choose `pch` to be a value between 21 and 25, try it).
- Then, add the line using `abline()`, put the line width = 2 to make it more visible. Do not forget to title the Figure).

4. Now make the same plot but color the points with respect to their real labels (the variable `Purchased`). From this figure, count the number of the false positive predictions and compare it to the value obtained in the confusion matrix.

Linear Discriminant Analysis (LDA)

Let us apply linear discriminant analysis (LDA) now. First we will make use of the `lda()` function in the package `MASS`. Second, you are going to create the model and predict the classes by yourself without using the `lda()` function. And we will visualize the decision boundary of LDA.

5. Fit a LDA model of `Purchased` in function of `Age` and `EstimatedSalary`. Name the model `classifier.lda`.

```
library(MASS)
classifier.lda <- lda(Purchased~Age+EstimatedSalary, data=training_set)
```

6. Call `classifier.lda` and see what does it compute.

Plus: If you enter the following you will be returned with a list of summary information concerning the computation:

```
classifier.lda$prior
classifier.lda$means
```

7. On the test set, predict the probability of purchasing the product by the users using the model `classifier.lda`. Remark that when we predict using LDA, we obtain a list instead of a matrix, do `str()` for your predictions to see what do you get.

Remark: we get the predicted class here, without being obligated to round the predictions as we did for logistic regression.

8. Compute the confusion matrix and compare the predictions results obtained by LDA to the ones obtained by logistic regression. What do you remark?

(Hint: compare the accuracy)

9. Now let us plot the decision boundary obtained with LDA. You saw in the course that decision boundary for LDA represent the set of values x where $\delta_k(x) = \delta_c(x)$. Recall that

$$\delta_k(X) = x^T \Sigma^{-1} \mu_k - \frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k + \log \pi_k$$

Here in our case, we have 2 classes ($K = 2$) and 2 predictors ($p = 2$). So the decision boundary (which is linear in the case of LDA, and line in our case since $p = 2$) will verify the equation $\delta_0(x) = \delta_1(x)$. Since we have two classes “0” and “1”. In the case of LDA this leads to linear boundary and is easy to be plotted. But in more complicated cases it is difficult to manually simplify the equations and plot the decision boundary. Anyway, there is a smart method to plot (but a little bit costly) the decision boundary in R using the function `contour()`, the corresponding code is the following (you must adapt it and use it to plot your decision boundary):

```
# create a grid corresponding to the scales of Age and EstimatedSalary
# and fill this grid with lot of points
X1 = seq(min(training_set[, 1]) - 1, max(training_set[, 1]) + 1, by = 0.01)
X2 = seq(min(training_set[, 2]) - 1, max(training_set[, 2]) + 1, by = 0.01)
grid_set = expand.grid(X1, X2)
# Adapt the variable names
colnames(grid_set) = c('Age', 'EstimatedSalary')

# plot 'Estimated Salary' ~ 'Age'
plot(test_set[, -3],
     main = 'Decision Boundary LDA',
     xlab = 'Age', ylab = 'Estimated Salary',
     xlim = range(X1), ylim = range(X2))

# color the plotted points with their real label (class)
points(test_set, pch = 21, bg = ifelse(test_set[, 3] == 1, 'green4', 'red3'))

# Make predictions on the points of the grid, this will take some time
pred_grid = predict(classifier.lda, newdata = grid_set)$class

# Separate the predictions by a contour
contour(X1, X2, matrix(as.numeric(pred_grid), length(X1), length(X2)), add = TRUE)
```

10. Now let us build a LDA model for our data set without using the `lda()` function. You are free to do it by creating a function or without creating one. Go back to question 6 and see what did you obtain by using `lda()`. It computes the prior probability of group membership and the estimated group means for each of the two groups. Additional information that is not provided, but may be important, is the single covariance matrix that is being used for the various groupings.

In LDA, we compute for every observation x its discriminant score $\delta_k(x)$. Then we attribute x to the class that has the highest δ . Recall that

$$\delta_k(x) = x^T \Sigma^{-1} \mu_k - \frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k + \log \pi_k$$

So to compute $\delta_k(x)$ we need to estimate π_k , μ_k and Σ .

Note that

$$x = \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}$$

and here X_1 =Age and X_2 =EstimatedSalary.

So let us do it step by step, first we will do the estimates:

10.1 Subset the training set into two sets: `class0` where `Purchased = 0` and `class1` where `Purchased = 1`).

10.2 Compute π_0 and π_1 .

$$\pi_i = N_i/N, \text{ where } N_i \text{ is the number of data points in group } i$$

10.3 Compute μ_0 and μ_1 .

$$\mu_0 = \begin{pmatrix} \mu_0(X_1) \\ \mu_0(X_2) \end{pmatrix} \text{ and } \mu_1 = \begin{pmatrix} \mu_1(X_1) \\ \mu_1(X_2) \end{pmatrix}$$

where, for example, $\mu_0(X_1)$ is the mean of the variable X_1 in the group 0 (the subset `class0`).

10.4 Compute Σ . In the case of two classes like here, it is computed by calculating the following:

$$\Sigma = \frac{(N_0 - 1)\Sigma_0 + (N_1 - 1)\Sigma_1}{N_0 + N_1 - 2}$$

where Σ_i is the estimated covariance matrix for specific group i .

Remark: Recall that in LDA we use the same Σ . But in QDA we do not.

10.5. Now that we have computed all the needed estimates, we can calculate $\delta_0(x)$ and $\delta_1(x)$ for any observation x . And we will attribute x to the class with the highest δ . First, try it for x where $x^T = (1, 1.5)$, what is class prediction for this specific x ?

10.6. Compute the discriminant scores δ for the test set (a matrix 100×2), predict the classes and compare your results with the results obtained with the `lda()` function.

Quadratic Discriminant Analysis (QDA)

Training and assessing a QDA model in R is very similar in syntax to training and assessing a LDA model. The only difference is in the function name `qda()`

11. Fit a QDA model of `Purchased` in function of `Age` and `EstimatedSalary`. Name the model `classifier.qda`.

```
# qda() is a function of library(MASS)
classifier.qda <- qda(Purchased~., data = training_set)
```

12. Make predictions on the `test_set` using the QDA model `classifier.qda`. Show the computation matrix and compare the results with the predictions obtained using the LDA model `classifier.lda`.

13. Plot the decision boundary obtained with QDA. Color the points with the real labels.

Comparison

14. In order to compare the methods we used, plot on the same Figure the ROC curve for each classifier we fitted and compare the correspondent AUC. What was the best model for this dataset?

Remark: If you use the `ROCR` package:

- For Logistic regression, use the predicted probabilities in the `prediction()` (and not the round values “0” or “1”).

- For LDA and QDA, put `pred.lda$posterior[,2]` in the `prediction()` function (those are the posterior probabilities that observations belong to class “1”).

PW 5

This session is special. You are given a dataset on moodle, go download it and analyze it. You must submit a report (html) of your analysis at the end of the session. This report is the most important one for your evaluation.

The data analysis must include all the following steps: importing the dataset, exploring the dataset and describing it, data preprocessing, data splitting, building models and assessing models.

Here are some rules for this special session:

- The dataset will be available on moodle during the session.
- You can ask questions. But the professor will not answer all of your questions. It depends on the question.
- Of course every student must work individually and no discussions are allowed.
- You have the right to access internet, the course's website, and even googling some R tips for your codes. But you are not allowed to open any Social Network website neither your email. If you open one of these you will get directly zero.
- The professor has the right to verify by himself if you are opening any Social network/email website.
- The report must be written in english of course.
- There won't be a quiz in this special session in order to give you the complete 3 hours to analyze the dataset. But you must apply SVM (chapter 5) if there is a need. The quiz of week 6 will be about SVM (chapter 5) and about the upcoming chapter 6.
- Your report must be clear. Every step or decision you make must be explained. Your code must be commented and your results must be interpreted.

Good Luck!

Part IV

Unsupervised Learning

Chapter 6

Dimensionality Reduction

6.1 Unsupervised Learning

Previously we considered supervised learning methods such as regression and classification, where we typically have access to a set of p features X_1, X_2, \dots, X_p , measured on n observations, and a response Y also measured on those same n observations (what we call **labels**). The goal was then to predict Y using X_1, X_2, \dots, X_p . From now on we will instead focus on **unsupervised** learning, a set of statistical tools where we have only a set of features X_1, X_2, \dots, X_p measured on n observations. We are not interested in prediction, because we do not have an associated response variable Y . Rather, the goal is to discover interesting things about the measurements on X_1, X_2, \dots, X_p . Is there an informative way to visualize the data? Can we discover subgroups among the variables or among the observations? Unsupervised learning refers to a diverse set of techniques for answering questions such as these. In this chapter, we will focus on a particular type of unsupervised learning: Principal Components Analysis (PCA), a tool used for data visualization or data pre-processing before supervised techniques are applied. In the next chapters, we will talk about clustering, another particular type of unsupervised learning. Clustering is a broad class of methods for discovering unknown subgroups in data.

Unsupervised learning is often much more challenging than supervised learning. The exercise tends to be more subjective, and there is no simple goal for the analysis, such as prediction of a response. Unsupervised learning is often performed as part of an exploratory data analysis. It is hard to assess the results obtained from unsupervised learning methods. If we fit a predictive model using a supervised learning technique, then it is possible to check our work by seeing how well our model predicts the response Y on observations not used in fitting the model. But in unsupervised learning, there is no way to check our work because we don't know the true answer: the problem is unsupervised.

6.2 Principal Components Analysis

The central idea of principal component analysis (PCA) is to reduce the dimensionality of a data set consisting of a large number of interrelated variables, while retaining as much as possible of the variation present in the data set. This is achieved by transforming to a new set of variables, the principal components (PCs), which are uncorrelated, and which are ordered so that the first few retain most of the variation present in all of the original variables.

Suppose that we wish to visualize n observations with measurements on a set of p features, X_1, X_2, \dots, X_p , as part of an exploratory data analysis. We could do this by examining two-dimensional scatterplots of the data, each of which contains the n observations' measurements on two of the features. However, there are $C_p^2 = p(p-1)/2$ such scatterplots. For example, with $p = 10$ there are 45 plots! If p is large, then it will

certainly not be possible to look at all of them; moreover, most likely none of them will be informative since they each contain just a small fraction of the total information present in the data set. Clearly, a better method is required to visualize the n observations when p is large. In particular, we would like to find a low-dimensional representation of the data that captures as much of the information as possible. PCA provides a tool to do just this.

PCA finds a low-dimensional representation of a data set that contains as much as possible of the variation. The idea is that each of the n observations lives in p -dimensional space, but not all of these dimensions are equally interesting. PCA seeks a small number of dimensions that are as interesting as possible, where the concept of interesting is measured by the amount that the observations vary along each dimension. Each of the dimensions found by PCA is a **linear combination of the p features**. We now explain the manner in which these dimensions, or principal components, are found.

6.3 Principal Components

Notations and Procedure

Suppose that we have a random vector of the features X .

$$\mathbf{X} = \begin{pmatrix} X_1 \\ X_2 \\ \vdots \\ X_p \end{pmatrix}$$

with population variance-covariance matrix

$$\text{var}(\mathbf{X}) = \Sigma = \begin{pmatrix} \sigma_1^2 & \sigma_{12} & \cdots & \sigma_{1p} \\ \sigma_{21} & \sigma_2^2 & \cdots & \sigma_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{p1} & \sigma_{p2} & \cdots & \sigma_p^2 \end{pmatrix}$$

Consider the linear combinations

$$\begin{aligned} Y_1 &= a_{11}X_1 + a_{12}X_2 + \cdots + a_{1p}X_p \\ Y_2 &= a_{21}X_1 + a_{22}X_2 + \cdots + a_{2p}X_p \\ &\vdots \\ Y_p &= a_{p1}X_1 + a_{p2}X_2 + \cdots + a_{pp}X_p \end{aligned}$$

Note that Y_i is a function of our random data, and so is also random. Therefore it has a population variance

$$\text{var}(Y_i) = \sum_{k=1}^p \sum_{l=1}^p a_{ik}a_{il}\sigma_{kl} = \mathbf{a}_i^T \Sigma \mathbf{a}_i$$

Moreover, Y_i and Y_j will have a population covariance

$$\text{cov}(Y_i, Y_j) = \sum_{k=1}^p \sum_{l=1}^p a_{ik}a_{jl}\sigma_{kl} = \mathbf{a}_i^T \Sigma \mathbf{a}_j$$

and a correlation

$$\text{cor}(Y_i, Y_j) = \frac{\text{cov}(Y_i, Y_j)}{\sigma_i^2 \sigma_j^2}$$

Here the coefficients a_{ij} are collected into the vector

$$\mathbf{a}_i = \begin{pmatrix} a_{i1} \\ a_{i2} \\ \vdots \\ a_{ip} \end{pmatrix}$$

The coefficients a_{ij} are also called loadings of the principal component i and \mathbf{a}_i is a principal component loading vector.

- The total variation of X is the trace of the variance-covariance matrix Σ .
- The trace of Σ is the sum of the variances of the individual variables.
- $\text{trace}(\Sigma) = \sigma_1^2 + \sigma_2^2 + \dots + \sigma_p^2$

First Principal Component (PC₁): Y_1

The first principal component is the normalized linear combination of the features X_1, X_2, \dots, X_p that has maximum variance (among all linear combinations), so it accounts for as much variation in the data as possible.

Specifically we will define coefficients $a_{11}, a_{12}, \dots, a_{1p}$ for that component in such a way that its variance is maximized, subject to the constraint that the sum of the squared coefficients is equal to one (that is what we mean by normalized). This constraint is required so that a unique answer may be obtained.

More formally, select $a_{11}, a_{12}, \dots, a_{1p}$ that maximizes

$$\text{var}(Y_1) = \mathbf{a}_1^T \Sigma \mathbf{a}_1 = \sum_{k=1}^p \sum_{l=1}^p a_{1k} a_{1l} \sigma_{kl}$$

subject to the constraint that

$$\sum_{j=1}^p a_{1j}^2 = \mathbf{a}_1^T \mathbf{a}_1 = 1$$

Second Principal Component (PC₂): Y_2

The second principal component is the linear combination of the features X_1, X_2, \dots, X_p that accounts for as much of the remaining variation as possible, with the constraint that the correlation between the first and second component is 0. So the second principal component has maximal variance out of all linear combinations that are uncorrelated with Y_1 .

To compute the coefficients of the second principal component, we select $a_{21}, a_{22}, \dots, a_{2p}$ that maximizes the variance of this new component

$$\text{var}(Y_2) = \sum_{k=1}^p \sum_{l=1}^p a_{2k} a_{2l} \sigma_{kl} = \mathbf{a}_2^T \Sigma \mathbf{a}_2$$

subject to:

- The constraint that the sums of squared coefficients add up to one, $\sum_{j=1}^p a_{2j}^2 = \mathbf{a}_2^T \mathbf{a}_2 = 1$.
- Along with the additional constraint that these two components will be uncorrelated with one another:

$$\text{cov}(Y_1, Y_2) = \mathbf{a}_1^T \Sigma \mathbf{a}_2 = \sum_{k=1}^p \sum_{l=1}^p a_{1k} a_{2l} \sigma_{kl} = 0$$

All subsequent principal components have this same property: they are linear combinations that account for as much of the remaining variation as possible and they are not correlated with the other principal components.

We will do this in the same way with each additional component. For instance:

i^{th} **Principal Component (PC_{*i*}):** Y_i

We select $a_{i1}, a_{i2}, \dots, a_{ip}$ that maximizes

$$\text{var}(Y_i) = \sum_{k=1}^p \sum_{l=1}^p a_{ik} a_{il} \sigma_{kl} = \mathbf{a}_i^T \Sigma \mathbf{a}_i$$

subject to the constraint that the sums of squared coefficients add up to one, along with the additional constraint that this new component will be uncorrelated with all the previously defined components:

$$\begin{aligned} \sum_{j=1}^p a_{ij}^2 \mathbf{a}_i^T \mathbf{a}_i &= \mathbf{a}_i^T \mathbf{a}_i = 1 \\ \text{cov}(Y_1, Y_i) &= \sum_{k=1}^p \sum_{l=1}^p a_{1k} a_{il} \sigma_{kl} = \mathbf{a}_1^T \Sigma \mathbf{a}_i = 0 \\ \text{cov}(Y_2, Y_i) &= \sum_{k=1}^p \sum_{l=1}^p a_{2k} a_{il} \sigma_{kl} = \mathbf{a}_2^T \Sigma \mathbf{a}_i = 0 \\ &\vdots \\ \text{cov}(Y_{i-1}, Y_i) &= \sum_{k=1}^p \sum_{l=1}^p a_{i-1,k} a_{il} \sigma_{kl} = \mathbf{a}_{i-1}^T \Sigma \mathbf{a}_i = 0 \end{aligned}$$

Therefore all principal components are uncorrelated with one another.

6.4 How do we find the coefficients?

How do we find the coefficients a_{ij} for a principal component? The solution involves the **eigenvalues** and **eigenvectors** of the variance-covariance matrix Σ .

Let $\lambda_1, \dots, \lambda_p$ denote the eigenvalues of the variance-covariance matrix Σ . These are ordered so that λ_1 has the largest eigenvalue and λ_p is the smallest.

$$\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_p$$

We are also going to let the vectors $\mathbf{a}_1, \dots, \mathbf{a}_p$ denote the corresponding eigenvectors.

It turns out that the elements for these eigenvectors will be the coefficients of the principal components.

The elements for the eigenvectors of Σ are the coefficients of the principal components.

The variance for the i th principal component is equal to the i th eigenvalue.

$$\text{var}(Y_i) = \text{var}(a_{i1}X_1 + a_{i2}X_2 + \dots + a_{ip}X_p) = \lambda_i$$

Moreover, the principal components are uncorrelated with one another.

$$\text{cov}(Y_i, Y_j) = 0$$

The variance-covariance matrix may be written as a function of the eigenvalues and their corresponding eigenvectors. In fact, the variance-covariance matrix can be written as the sum over the p eigenvalues, multiplied by the product of the corresponding eigenvector times its transpose as shown in the following expression

$$\Sigma = \sum_{i=1}^p \lambda_i \mathbf{a}_i \mathbf{a}_i^T$$

If $\lambda_{k+1}, \lambda_{k+2}, \dots, \lambda_p$ are small, we might approximate Σ by

$$\Sigma \cong \sum_{i=1}^k \lambda_i \mathbf{a}_i \mathbf{a}_i^T$$

Earlier in the chapter we defined the total variation of X as the trace of the variance-covariance matrix. This is also equal to the sum of the eigenvalues as shown below:

$$\begin{aligned} \text{trace}(\Sigma) &= \sigma_1^2 + \sigma_2^2 + \dots + \sigma_p^2 \\ &= \lambda_1 + \lambda_2 + \dots + \lambda_p \end{aligned}$$

This will give us an interpretation of the components in terms of the amount of the full variation explained by each component. The proportion of variation explained by the i th principal component is then going to be defined to be the eigenvalue for that component divided by the sum of the eigenvalues. In other words, the i th principal component explains the following proportion of the total variation:

$$\frac{\lambda_i}{\lambda_1 + \lambda_2 + \dots + \lambda_p}$$

A related quantity is the proportion of variation explained by the first k principal component. This would be the sum of the first k eigenvalues divided by its total variation.

$$\frac{\lambda_1 + \lambda_2 + \dots + \lambda_k}{\lambda_1 + \lambda_2 + \dots + \lambda_p}$$

In practice, these proportions are often expressed as percentages.

Naturally, if the proportion of variation explained by the first k principal components is large, then not much information is lost by considering only the first k principal components.

Why It May Be Possible to Reduce Dimensions

When we have correlations (multicollinearity) between the features, the data may more or less fall on a line or plane in a lower number of dimensions. For instance, imagine a plot of two features that have a nearly perfect correlation. The data points will fall close to a straight line. That line could be used as a new (one-dimensional) axis to represent the variation among data points.

All of this is defined in terms of the population variance-covariance matrix Σ which is unknown. However, we may estimate Σ by the sample variance-covariance matrix which is given in the standard formula here:

$$\mathbf{S} = \frac{1}{n-1} \sum_{i=1}^n (\mathbf{X}_i - \bar{\mathbf{x}})(\mathbf{X}_i - \bar{\mathbf{x}})^T$$

Procedure

Compute the eigenvalues $\hat{\lambda}_1, \hat{\lambda}_2, \dots, \hat{\lambda}_p$ of the sample variance-covariance matrix \mathbf{S} , and the corresponding eigenvectors $\hat{\mathbf{a}}_1, \hat{\mathbf{a}}_2, \dots, \hat{\mathbf{a}}_p$.

Then we will define our estimated principal components using the eigenvectors as our coefficients:

$$\begin{aligned} \hat{Y}_1 &= \hat{a}_{11}X_1 + \hat{a}_{12}X_2 + \dots + \hat{a}_{1p}X_p \\ \hat{Y}_2 &= \hat{a}_{21}X_1 + \hat{a}_{22}X_2 + \dots + \hat{a}_{2p}X_p \\ &\vdots \\ \hat{Y}_p &= \hat{a}_{p1}X_1 + \hat{a}_{p2}X_2 + \dots + \hat{a}_{pp}X_p \end{aligned}$$

Generally, we only retain the first k principal component. There are a number of criteria that may be used to decide how many components should be retained:

1. To obtain the simplest possible interpretation, we want k to be as small as possible. If we can explain most of the variation just by **two** principal components then this would give us a much simpler description of the data.
2. Retain the first k components which explain a “large” proportion of the total variation, say 70 – 80%.
3. Examine a scree plot. This is a plot of the eigenvalues versus the component number. The idea is to look for the “elbow” which corresponds to the point after which the eigenvalues decrease more slowly. Adding components after this point explains relatively little more of the variance. See the next figure for an example of a scree plot.

Scree plot showing eigenvalue by number of principal component.

6.5 Standardization of the features

If we use the raw data, the principal component analysis will tend to give more emphasis to the variables that have higher variances than to those variables that have very low variances.

In effect the results of the analysis will depend on what units of measurement are used to measure each variable. That would imply that a principal component analysis should only be used with the raw data if all variables have the same units of measure. And even in this case, only if you wish to give those variables which have higher variances more weight in the analysis.

- The results of principal component analysis depend on the scales at which the variables are measured.
- Variables with the highest sample variances will tend to be emphasized in the first few principal components.
- Principal component analysis using the covariance function should only be considered if all of the variables have the same units of measurement.

If the variables either have different units of measurement, or if we wish each variable to receive equal weight in the analysis, then the variables should be **standardized** (scaled) before a principal components analysis is carried out. Standardize the variables by subtracting its mean from that variable and dividing it by its standard deviation:

$$Z_{ij} = \frac{X_{ij} - \bar{x}_j}{\sigma_j}$$

where

- X_{ij} = Data for variable j in sample unit i
- \bar{x}_j = Sample mean for variable j
- σ_j = Sample standard deviation for variable j

Note: Z_j has mean = 0 and variance = 1.

The variance-covariance matrix of the standardized data is equal to the correlation matrix for the unstandardized data. Therefore, principal component analysis using the standardized data is equivalent to principal component analysis using the correlation matrix.

6.6 Projection of the data

Scores

Using the coefficients (loadings) of every principal component, we can project the observations on the axis of the principal component, those projections are called scores. For example, the scores of the first principal component are

$$\forall 1 \leq i \leq n \quad \hat{Y}_1^i = \hat{a}_{11}X_1^i + \hat{a}_{12}X_2^i + \cdots + \hat{a}_{1p}X_p^i$$

(X_1^i is the value of feature 1 for the observation i)

This can be written for all observations and all the principal components using the matrix formulation

$$\hat{\mathbf{Y}} = \hat{\mathbf{A}}\mathbf{X}$$

where $\hat{\mathbf{A}}$ is the matrix of the coefficients \hat{a}_{ij} .

Visualization

Once we have computed the principal components, we can plot them against each other in order to produce low-dimensional views of the data.

We can plot the score vector Y_1 against Y_2 , Y_1 against Y_3 , Y_2 against Y_3 , and so forth. Geometrically, this amounts to projecting the original data down onto the subspace spanned by \mathbf{a}_1 , \mathbf{a}_2 , and \mathbf{a}_3 , and plotting the projected points.

To interpret the results obtained by PCA, we plot on the same figure both the principal component scores and the loading vectors. This figure is called a biplot. An example is given later in this chapter.

Extra

- You can read this tutorial  . In the document, there is an introduction about the mathematical concepts used in PCA. Plus a detailed example of PCA.
- You can watch these videos for a nice explanation of PCA  1  2.

6.7 Case study

Employement in European countries in the late 70s

The purpose of this case study is to reveal the structure of the job market and economy in different developed countries. The final aim is to have a meaningful and rigorous plot that is able to show the most important features of the countries in a concise form.

The dataset `eurojob` (download) contains the data employed in this case study. It contains the percentage of workforce employed in 1979 in 9 industries for 26 European countries. The industries measured are:

- Agriculture (**Agr**)
- Mining (**Min**)
- Manufacturing (**Man**)
- Power supply industries (**Pow**)
- Construction (**Con**)
- Service industries (**Ser**)
- Finance (**Fin**)
- Social and personal services (**Soc**)
- Transport and communications (**Tra**)

If the dataset is imported into **R** and the case names are set as **Country** (important in order to have only numerical variables), then the data should look like this:

Table 6.1: The ‘eurojob’ dataset.

Country	Agr	Min	Man	Pow	Con	Ser	Fin	Soc	Tra
Belgium	3.3	0.9	27.6	0.9	8.2	19.1	6.2	26.6	7.2

EGerm	4.2	2.9	41.2	1.3	7.6	11.2	1.2	22.1	8.4
Hungary	21.7	3.1	29.6	1.9	8.2	9.4	0.9	17.2	8.0
Poland	31.1	2.5	25.7	0.9	8.4	7.5	0.9	16.1	6.9
Romania	34.7	2.1	30.1	0.6	8.7	5.9	1.3	11.7	5.0
USSR	23.7	1.4	25.8	0.6	9.2	6.1	0.5	23.6	9.3
Yugoslavia	48.7	1.5	16.8	1.1	4.9	6.4	11.3	5.3	4.0

Note: To set the case names as Country, we do

```
row.names(eurojob) <- eurojob$Country
eurojob$Country <- NULL
```

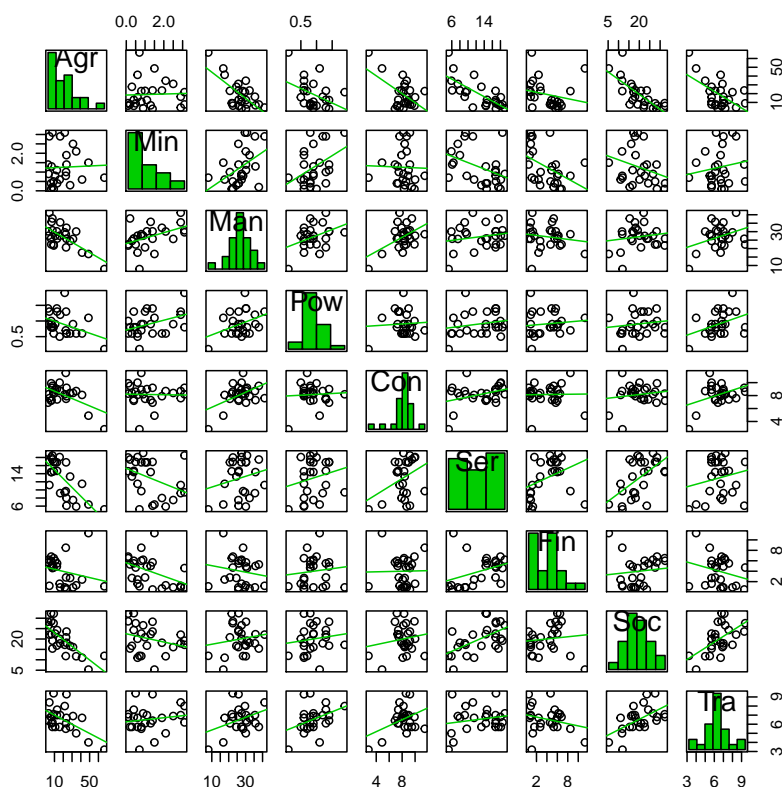

So far, we know how to compute summaries for each variable, and how to quantify and visualize relations between variables with the correlation matrix and the scatterplot matrix. But even for a moderate number of variables like this, their results are hard to process.

Summary of the data - marginal

                  diagonal = 'histogram')
```

We definitely need a way of visualizing and quantifying the relations between variables for a moderate to large amount of variables. PCA will be a handy way. Recall what PCA does:

1. Takes the data for the variables X_1, \dots, X_p .
2. Using this data, looks for new variables PC_1, \dots, PC_p such that:
 - PC_j is a **linear combination** of X_1, \dots, X_k , $1 \leq j \leq p$. This is, $PC_j = a_{1j}X_1 + a_{2j}X_2 + \dots + a_{pj}X_p$.

- PC_1, \dots, PC_p are **sorted decreasingly in terms of variance**. Hence PC_j has more variance than PC_{j+1} , $1 \leq j \leq p-1$,
 - PC_{j_1} and PC_{j_2} are **uncorrelated**, for $j_1 \neq j_2$.
 - PC_1, \dots, PC_p have the **same information**, measured in terms of **total variance**, as X_1, \dots, X_p .
3. Produces three key objects:
- **Variances of the PCs**. They are sorted decreasingly and give an idea of which PCs contain most of the information of the data (the ones with more variance).
 - **Weights of the variables in the PCs**. They give the interpretation of the PCs in terms of the original variables, as they are the coefficients of the linear combination. The weights of the variables X_1, \dots, X_p on the PC_j , a_{1j}, \dots, a_{pj} , are normalized: $a_{1j}^2 + \dots + a_{pj}^2 = 1$, $j = 1, \dots, p$. In R, they are called **loadings**.
 - **Scores of the data in the PCs**: this is the data with PC_1, \dots, PC_p variables instead of X_1, \dots, X_p . The **scores are uncorrelated**. Useful for knowing which PCs have more effect on a certain observation.

Hence, PCA rearranges our variables in an information-equivalent, but more convenient, layout where the variables are **sorted according to the amount of information they are able to explain**. From this position, the next step is clear: **stick only with a limited number of PCs such that they explain most of the information** (e.g., 70% of the total variance) and do dimension reduction. The effectiveness of PCA in practice varies from the structure present in the dataset. For example, in the case of highly dependent data, it could explain more than the 90% of variability of a dataset with tens of variables with just two PCs.

Let's see how to compute a full PCA in R.

PCA produces **uncorrelated** variables from the original set X_1, \dots, X_p . This implies that:

- The PCs are uncorrelated, **but not independent** (uncorrelated does not imply independent).
- An uncorrelated or independent variable in X_1, \dots, X_p will get a PC only associated to it. In the extreme case where all the X_1, \dots, X_p are uncorrelated, these coincide with the PCs (up to sign flips).

Based on the weights of the variables on the PCs, we can extract the following interpretation:

- PC1 is roughly a linear combination of **Agr**, with negative weight, and (**Man**, **Pow**, **Con**, **Ser**, **Soc**, **Tra**), with positive weights. So it can be interpreted as an indicator of the kind of economy of the country: agricultural (negative values) or industrial (positive values).

- PC2 has negative weights on (Min, Man, Pow, Tra) and positive weights in (Ser, Fin, Soc). It can be interpreted as the contrast between relatively large or small service sectors. So it tends to be negative in communist countries and positive in capitalist countries.

The interpretation of the PCs involves inspecting the weights and interpreting the linear combination of the original variables, which might be separating between two clear characteristics of the data

To conclude, let's see how we can represent our original data into a plot called biplot that summarizes all the analysis for two PCs.

```
# Biplot - plot together the scores for PC1 and PC2 and the
# variables expressed in terms of PC1 and PC2
biplot(pca)
```

PW 6

The Iris Dataset

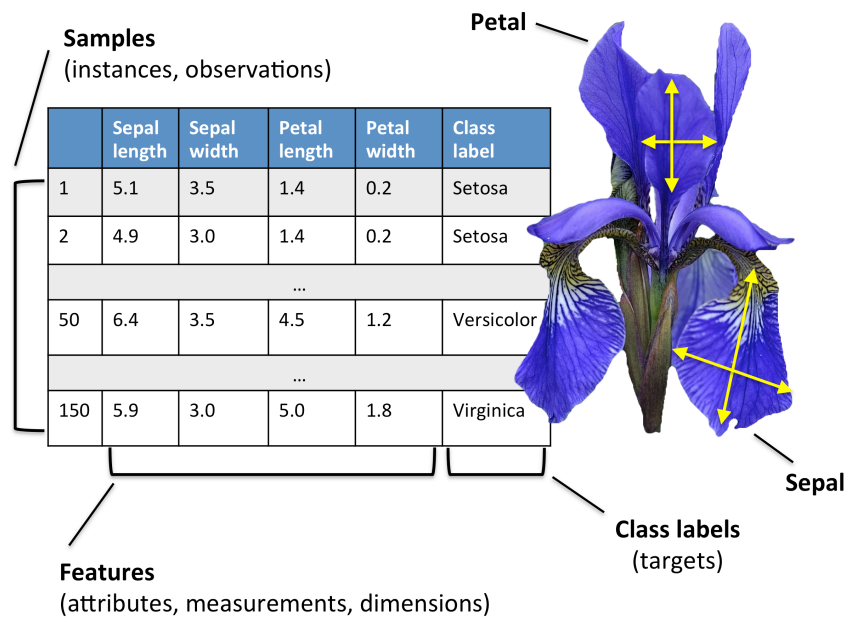

The iris dataset contains measurements for 150 iris flowers from three different species.

The three classes in the Iris dataset are:

1. Iris-setosa ($n_1 = 50$)
2. Iris-versicolor ($n_2 = 50$)
3. Iris-virginica ($n_3 = 50$)

And the four features in Iris dataset are:

1. sepal length in cm
2. sepal width in cm
3. petal length in cm
4. petal width in cm

Building the PCA approach

Summary of the PCA Approach:

- Standardize the data.
- Obtain the Eigenvectors and Eigenvalues from the covariance matrix or correlation matrix.
- Sort eigenvalues in descending order and choose the k eigenvectors that correspond to the k largest eigenvalues, where k is the number of dimensions of the new feature subspace ($k \leq p$).
- Construct the projection matrix \mathbf{A} from the selected k eigenvectors.
- Transform the original dataset X via \mathbf{A} to obtain a k -dimensional feature subspace \mathbf{Y} .

Data pre-processing

1. Download the iris dataset from here and import it into R.
2. Show the last 5 rows of the iris dataset.

Exploratory analysis

3. To explore how the 3 different flower classes are distributed along the 4 different features, visualize them via histograms.

```
# load ggplot2, install it if needed
library(ggplot2)

# histogram of sepal_length
ggplot(iris, aes(x=sepal_length, fill=class)) +
  geom_histogram(binwidth=.2, alpha=.5)
# histogram of sepal_width
ggplot(iris, aes(x=sepal_width, fill=class)) +
  geom_histogram(binwidth=.2, alpha=.5)
# histogram of petal_length
ggplot(iris, aes(x=petal_length, fill=class)) +
  geom_histogram(binwidth=.2, alpha=.5)
# histogram of petal_width
ggplot(iris, aes(x=petal_width, fill=class)) +
  geom_histogram(binwidth=.2, alpha=.5)
```

4. Compare the means and the quartiles of the 3 different flower classes for the 4 different features (Plot 4 boxplots into the same figure).
5. Split the iris dataset into data X and class labels y .

The iris dataset is now stored in form of a 150×4 matrix where the columns are the different features, and every row represents a separate flower sample. Each sample row X^i can be pictured as a 4-dimensional vector

$$(X^i)^T = \begin{pmatrix} X_1^i \\ X_2^i \\ X_3^i \\ X_4^i \end{pmatrix} = \begin{pmatrix} \text{sepal length} \\ \text{sepal width} \\ \text{petal length} \\ \text{petal width} \end{pmatrix}$$

Eigendecomposition - Computing Eigenvectors and Eigenvalues

The eigenvectors and eigenvalues of a covariance (or correlation) matrix represent the “core” of a PCA: The eigenvectors (principal components) determine the directions of the new feature space, and the eigenvalues determine their magnitude. In other words, the eigenvalues explain the variance of the data along the new feature axes.

Standardizing

6. Scale the 4 features. Store the scaled matrix into a new one (for example, name it `x_scaled`).

Covariance Matrix

7. The classic approach to PCA is to perform the eigendecomposition on the covariance matrix Σ , which is a $p \times p$ matrix where each element represents the covariance between two features. Compute the Covariance Matrix of the scaled features (Print the results).

We can summarize the calculation of the covariance matrix via the following matrix equation:

$$\Sigma = \frac{1}{n-1} ((\mathbf{X} - \bar{\mathbf{X}})^T (\mathbf{X} - \bar{\mathbf{X}}))$$

where $\bar{\mathbf{X}}$ is the mean vector $\bar{\mathbf{X}} = \frac{1}{n} \sum_{k=1}^n x_k$.

The mean vector is a p -dimensional vector where each value in this vector represents the sample mean of a feature column in the dataset.

8. Perform an eigendecomposition on the covariance matrix. Compute the Eigenvectors and the Eigenvalues (you can use the `eigen()` function). What do you obtain?

Correlation Matrix

Especially, in the field of “Finance”, the correlation matrix typically used instead of the covariance matrix. However, the eigendecomposition of the covariance matrix (if the input data was standardized) yields the same results as a eigendecomposition on the correlation matrix, since the correlation matrix can be understood as the normalized covariance matrix.

9. Perform an eigendecomposition of the standardized data based on the correlation matrix.

10. Perform an eigendecomposition of the raw data based on the correlation matrix. Compare the obtained results with the previous question.

We should see that all three approaches yield the same eigenvectors and eigenvalue pairs:

- Eigendecomposition of the covariance matrix after standardizing the data.
- Eigendecomposition of the correlation matrix.
- Eigendecomposition of the correlation matrix after standardizing the data.

Selecting Principal Components

The `eigen()` function will, by default, sort the eigenvalues in decreasing order.

Explained Variance

11. Calculate the individual explained variation and the cumulative explained variation of each principal component. Show the results.
12. Plot the individual explained variation. (scree plot)

Projection Matrix

13. Construct the projection matrix that will be used to transform the Iris data onto the new feature subspace.

The “projection matrix” is basically just a matrix of our concatenated top k eigenvectors. Here, the projection matrix \mathbf{A} is a 4×2 -dimensional matrix.

Projection Onto the New Feature Space

In this last step we will use the 4×2 -dimensional projection matrix \mathbf{A} to transform our samples (observations) onto the new subspace via the equation $\mathbf{Y} = \mathbf{X} \times \mathbf{A}$ where \mathbf{Y} is a 150×2 matrix of our transformed samples.

14. Compute \mathbf{Y} (Recall the \mathbf{Y} is the matrix of scores, \mathbf{A} is the matrix of loadings).

Visualization

15. Plot the observations on the new feature space. Name the axis PC1 and PC2.
16. On the same plot, color the observations (the flowers) with respect to their flower classes.

Verifications with `princomp()`

17. Use the `princomp()` function as explained in Chapter 6. Compare the first 5 scores obtained using `princomp()` with your results above.
18. Plot together the scores for PC1 and PC2 and the variables expressed in terms of PC1 and PC2 using `biplot()`.
29. Interpret the results.

Chapter 7

Clustering: kmeans

Clustering (or Cluster analysis) is the collection of techniques designed to find subgroups or clusters in a dataset of variables X_1, \dots, X_p . Depending on the similarities between the observations, these are partitioned in homogeneous groups as separated as possible between them. Clustering methods can be classified into two main categories:

- **Partition methods.** Given a fixed number of cluster k , these methods aim to assign each observation of X_1, \dots, X_p to a unique cluster, in such a way that the within-cluster variation is as small as possible (the clusters are as homogeneous as possible) while the between cluster variation is as large as possible (the clusters are as separated as possible).
- **Hierarchical methods.** These methods construct a hierarchy for the observations in terms of their similitudes. This results in a tree-based representation of the data in terms of a dendogram, which depicts how the observations are clustered at different levels – from the smallest groups of one element to the largest representing the whole dataset.

In this chapter we will see the basics of the most well-known **partition method**, namely k -means clustering.

7.1 Introduction

Clustering (or Cluster analysis) is the process of partitioning a set of data objects (observations) into subsets. Each subset is a **cluster**, such that objects in a cluster are similar to one another, yet dissimilar to objects in other clusters.

The set of clusters resulting from a cluster analysis can be referred to as a clustering. In this context, different clustering methods may generate different clusterings on the same data set. The partitioning is not performed by humans, but by the clustering algorithm. Hence, clustering is useful in that it can lead to the discovery of previously unknown groups within the data.

Example: Imagine a Director of Customer Relationships at an Electronics magazine, and he has five managers working for him. He would like to organize all the company's customers into five groups so that each group can be assigned to a different manager. Strategically, he would like that the customers in each group are as similar as possible. Moreover, two given customers having very different business patterns should not be placed in the same group. His intention behind this business strategy is to develop customer relationship campaigns that specifically target each group, based on common features shared by the customers per group. Unlike in classification, the class **label** of each customer is unknown. He needs to discover these groupings. Given a large number of customers and many attributes describing customer profiles, it can be very costly or even infeasible to have a human study the data and manually come up with a way to partition the customers into strategic groups. He needs a clustering tool to help.

Clustering has been widely used in many applications such as business intelligence, image pattern recognition, Web search, biology, and security. In business intelligence, clustering can be used to organize a large number of customers into groups, where customers within a group share strong similar characteristics. In image recognition, clustering can be used to discover clusters or “subclasses” in handwritten character recognition systems. Suppose we have a data set of handwritten digits, where each digit is labeled as either 1, 2, 3, and so on. Clustering has also found many applications in Web search. For example, a keyword search may often return a very large number of hits (i.e., pages relevant to the search) due to the extremely large number of web pages. Clustering can be used to organize the search results into groups and present the results in a concise and easily accessible way. Moreover, clustering techniques have been developed to cluster documents into topics, which are commonly used in information retrieval practice.

Clustering is also called **data segmentation** in some applications because clustering partitions large data sets into groups according to their similarity.

As a branch of statistics, clustering has been extensively studied, with the main focus on distance-based cluster analysis. Clustering tools were proposed like *k-means*, *fuzzy c-means*, and several other methods.

Many clustering algorithms have been introduced in the literature. Since clusters can formally be seen as subsets of the data set, one possible classification of clustering methods can be according to whether the subsets are **fuzzy** or **crisp (hard)**.

Hard clustering

Hard clustering methods are based on classical set theory, and require that an object either does or does not belong to a cluster. Hard clustering means partitioning the data into a specified number of mutually exclusive subsets. The most common hard clustering method is *k-means*.

Fuzzy clustering

Fuzzy clustering methods, however, allow the objects to belong to several clusters simultaneously, with different degrees of membership. In many situations, fuzzy clustering is more natural than hard clustering. The most know technique of fuzzy clustering is the *fuzzy c-means*.

7.2 *k*-Means

If you have ever watched a group of tourists with a couple of tour guides who hold umbrellas up so that everybody can see them and follow them, then you have seen a dynamic version of the *k-means* algorithm. *k-means* is even simpler, because the data (playing the part of the tourists) does not move, only the tour guides move.

Suppose that we want to divide our input data into K categories, where we know the value of K . We allocate K cluster centres (also called prototypes or centroids) to our input space, and we would like to position these centres so that there is one cluster centre in the middle of each cluster. However, we don't know where the clusters are, let alone where their ‘middle’ is, so we need an algorithm that will find them. Learning algorithms generally try to minimize some sort of error, so we need to think of an error criterion that describes this aim. There are two things that we need to define:

A distance measure: In order to talk about distances between points, we need some way to measure distances. It is often the normal **Euclidean** distance, but there are other alternatives like Manhattan distance, Correlation distance, Chessboard distance and other.

The Euclidean distance: Let $x = (x_1, x_2)$ and $y = (y_1, y_2)$ two observations in a two-dimensional space. The Euclidean distance $d_{x,y}$ between x and y is

$$d_{x,y}^2 = (x_1 - y_1)^2 + (x_2 - y_2)^2$$

$$d_{x,y} = \sqrt{(x_1 - y_1)^2 + (x_2 - y_2)^2}$$

The mean average: Once we have a distance measure, we can compute the central point of a set of data points, which is the mean average. Actually, this is only true in Euclidean space, which is the one we are used to, where everything is nice and flat.

We can now think about a suitable way of positioning the cluster centres: we compute the mean point of each cluster, \mathbf{v}_k , $i = 1, \dots, K$, and put the cluster centre there. This is equivalent to minimizing the Euclidean distance (which is the sum-of-squares error) from each data point to its cluster centre. Then we decide which points belong to which clusters by associating each point with the cluster centre that it is closest to. This changes as the algorithm iterates. We start by positioning the cluster centres **randomly** though the input space, since we don't know where to put them, and we update their positions according to the data. We decide which cluster each data point belongs to by computing the distance between each data point and all of the cluster centres, and assigning it to the cluster that is the closest. For all the point that are assigned to a cluster, we then compute the mean of them, and move the cluster centre to that place. We iterate the algorithm until the cluster centres stop moving.

It is convenient at this point to define some notation to describe the assignment of data points to clusters. For each data point x_i , we introduce a corresponding set of binary indicator variables $u_{ki} \in 0, 1$, where $k = 1, \dots, K$ describing which of the K clusters the data point x_i is assigned to, so that if data point x_i is assigned to cluster k then $u_{ki} = 1$, and $u_{kj} = 0$ for $j \neq i$. This is known as the 1-of- K coding scheme. We can then define an objective function (and sometimes called a distortion measure), given by

$$J = \sum_{i=1}^N \sum_{k=1}^K u_{ki} \|x_i - \mathbf{v}_k\|^2$$

which represents the sum of the squares of the distances of each data point to its assigned vector \mathbf{v}_k . The goal is to find values for the $\{u_{ki}\}$ and the $\{\mathbf{v}_k\}$ so as to minimize J . We can do this through an iterative procedure in which each iteration involves two successive steps corresponding to successive optimizations with respect to the u_{ki} and the \mathbf{v}_k . The algorithm of k -means is described in the following algorithm:

The k -means algorithm

Data:

$\mathbf{X} = \{x_{ij}, i = 1, \dots, n, j = 1, \dots, p\}$

Result:

Cluster centres (Prototypes)

Initialization:

- Choose a value for K .
- Choose K random positions in the input space.
- Assign the prototypes \mathbf{v}_k to those positions

The k -means algorithm

Learning: repeat**for** each data point x_i **do**

- compute the distance to each prototype:

$$d_{ki} = \min_k d(x_i, \mathbf{v}_k)$$

- assign the data point to the nearest prototype with distance

$$u_{ki} = \begin{cases} 1 & \text{if } k = \operatorname{argmin}_j \|x_i - \mathbf{v}_j\|^2 \\ 0 & \text{otherwise} \end{cases}$$

for each prototype **do**

- move the position of the prototype to the mean of the points in that cluster:

$$\mathbf{v}_k = \frac{\sum_i u_{ki} x_i}{\sum_i u_{ki}}$$

Until the prototypes stop moving.

The k -means algorithm produces

- A final estimate of cluster centroids (i.e. their coordinates).
- An assignment of each point to their respective cluster.

The denominator in the expression $\mathbf{v}_k = \frac{\sum_i u_{ki} x_i}{\sum_i u_{ki}}$ is equal to the number of points assigned to cluster k , and so this result has a simple interpretation, namely set \mathbf{v}_k equal to the mean of all of the data points x_i assigned to cluster k . For this reason, the procedure is known as the k -means algorithm.

The two phases of re-assigning data points to clusters and re-computing the cluster means are repeated in turn until there is no further change in the assignments (or until some maximum number of iterations is exceeded). Because each phase reduces the value of the objective function J , convergence of the algorithm is assured. However, it may converge to a local rather than global minimum of J .

The k -means algorithm is illustrated using the Old Faithful data set ¹ in following figure.

¹Old Faithful, is a hydrothermal geyser in Yellowstone National Park in the state of Wyoming, U.S.A., and is a popular tourist attraction. Its name stems from the supposed regularity of its eruptions. The data set comprises 272 observations, each of which represents a single eruption and contains two variables corresponding to the duration in minutes of the eruption, and the time until the next eruption, also in minutes.

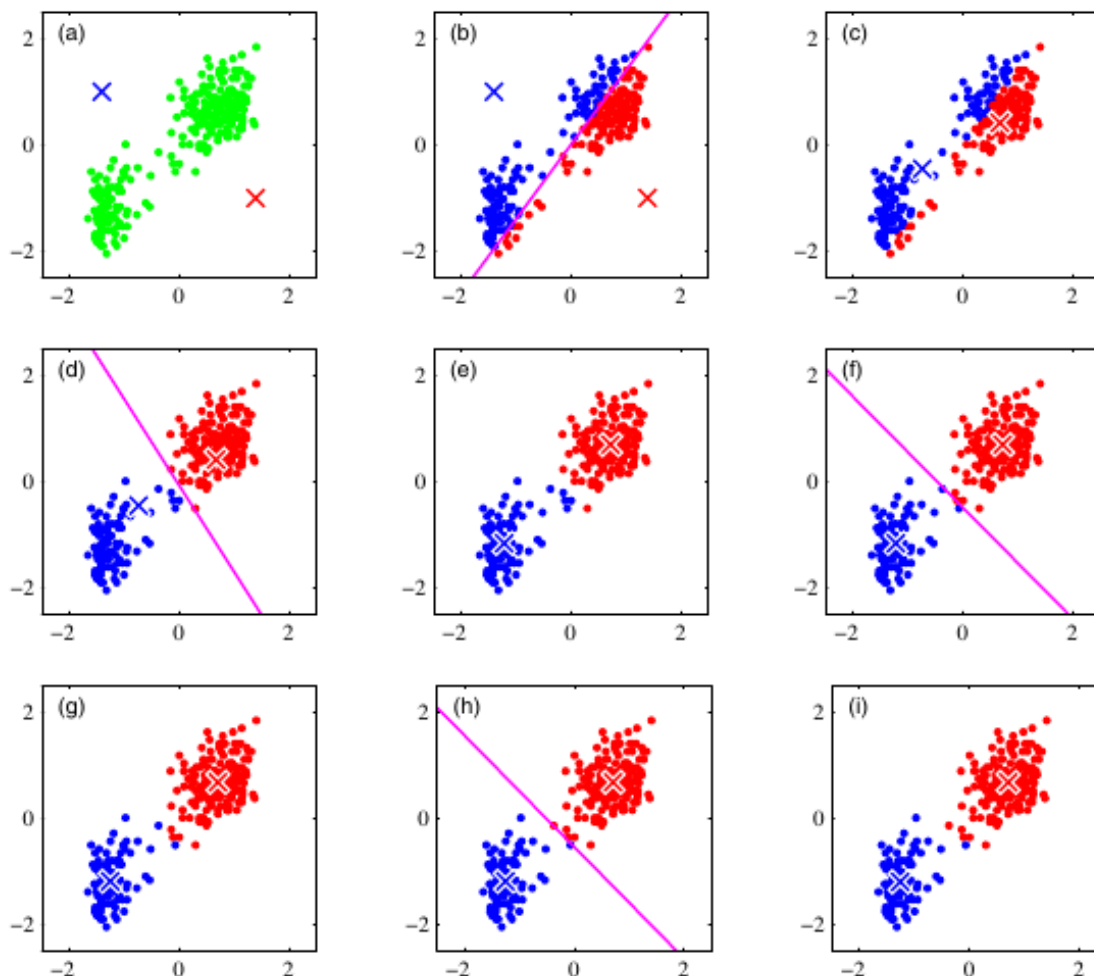

Figure 7.1: Illustration of the k -means algorithm using the re-scaled Old Faithful data set, where $k = 2$. We can see how the k -means algorithm works. (a) The first thing k -means has to do is assign an initial set of centroids. (b) The next stage in the algorithm assigns every point in the dataset to the closest centroid. (c) The next stage is the re-calculate the centroids based on the new cluster assignments of the data points. (d) Now we have completed one full cycle of the algorithm we can continue and re-assign points to their (new) closest cluster centroid. (e) And we can update the centroid positions one more time based on the re-assigned points. (g)(h)(f) The algorithm stops when we obtain the same results in consecutive iterations.

The k -means algorithm is illustrated using the Iris data set in following interactive figure². (Try to modify the X and Y variables and the numbers of chosen clusters and see the result)

7.3 k -means in R

We will use an example with simulated data to demonstrate how the k -means algorithm works. Here we simulate some data from three clusters and plot the dataset below.

²Made by Joseph J. Allaire <https://github.com/jjallaire>

```
set.seed(1234)
x <- rnorm(12,mean=rep(1:3,each=4),sd=0.2)
y <- rnorm(12,mean=rep(c(1,2,1),each=4),sd=0.2)
plot(x,y,col="blue",pch=19,cex=2)
text(x+0.05,y+0.05,labels=as.character(1:12))
```

Figure 7.2: Simulated dataset

The `kmeans()` function in R implements the *k*-means algorithm and can be found in the `stats` package, which comes with R and is usually already loaded when you start R. Two key parameters that you have to specify are `x`, which is a matrix or data frame of data, and `centers` which is either an integer indicating the number of clusters or a matrix indicating the locations of the initial cluster centroids. The data should be organized so that each row is an observation and each column is a variable or feature of that observation.

```
dataFrame <- data.frame(x,y)
kmeansObj <- kmeans(dataFrame,centers=3)
names(kmeansObj)
#ans> [1] "cluster"      "centers"      "totss"        "withinss"
#ans> [5] "tot.withinss" "betweeness"   "size"         "iter"
#ans> [9] "ifault"
```

You can see which cluster each data point got assigned to by looking at the `cluster` element of the list returned by the `kmeans()` function.

```
kmeansObj$cluster
#ans> [1] 3 3 3 3 1 1 1 1 2 2 2 2
```

Here is a plot of the *k*-means clustering solution.

```
plot(x,y,col=kmeansObj$cluster,pch=19,cex=2)
points(kmeansObj$centers,col=1:3,pch=3,cex=3,lwd=3)
```

Figure 7.3: *k*-means clustering solution

7.3.1 Cluster Validity, Choosing the Number of Clusters

The result of a clustering algorithm can be very different from each other on the same data set as the other input parameters of an algorithm can extremely modify the behavior and execution of the algorithm. The aim of the cluster validity is to find the partitioning that best fits the underlying data. Usually 2D data sets are used for evaluating clustering algorithms as the reader easily can verify the result. But in case of high dimensional data the visualization and visual validation is not a trivial tasks therefore some formal methods are needed.

The process of evaluating the results of a clustering algorithm is called cluster validity assessment. Two measurement criteria have been proposed for evaluating and selecting an optimal clustering scheme:

- **Compactness:** The member of each cluster should be as close to each other as possible. A common measure of compactness is the variance.
- **Separation:** The clusters themselves should be widely separated. There are three common approaches measuring the distance between two different clusters: distance between the closest member of the clusters, distance between the most distant members and distance between the centres of the clusters.

There are three different techniques for evaluating the result of the clustering algorithms, and several Validity measures are proposed: Validity measures are scalar indices that assess the goodness of the obtained partition. Clustering algorithms generally aim at locating well separated and compact clusters. When the number of clusters is chosen equal to the number of groups that actually exist in the data, it can be expected that the clustering algorithm will identify them correctly. When this is not the case, misclassifications appear, and the clusters are not likely to be well separated and compact. Hence, most cluster validity measures are designed to quantify the separation and the compactness of the clusters.

Check this answer on [stackoverflow](#) containing R code for several methods of computing an optimal value of k for *k*-means cluster analysis: [here](#).

PW 7

In this practical work we will apply the k -means clustering algorithm using the standard function `kmeans()` in R, we will use the dataset `La Liga 2015/2016`.

Use the following YAML header for the report that you must submit at the end of the session:

```
---
title: "Week 7"
subtitle: "$k$-means clustering"
author: LastName FirstName
date: "05/03/2017"
output:
  html_document:
    toc: true
    toc_depth: 2
    toc_float: true
    theme: readable
    highlight: pygments
---
```

k -means clustering

1. Download the dataset:  LaLiga 2015-2016 and import it into R. Put the argument `row.names` to 1.

You can import directly from my website (instead of downloading it..)

```
laliga <- read.csv("http://mghassany.com/MLcourse/datasets/la-liga-15-16.csv", row.names=1)
```

2. Print the first two rows of the dataset and the total number of features in this dataset.

`pointsCards`

3. We will first consider a smaller dataset to easily understand the results of k -means. Create a new dataset in which you consider only `Points` and `Yellow.cards` from the original dataset. Name it `pointsCards`
4. Apply k -means on `pointsCards`. Chose $k = 2$ clusters and put the number of iterations to 20. Store your results into `km`. (**Remark:** `kmeans()` uses a random initialization of the clusters, so the results may vary from one call to another. Use `set.seed()` to have reproducible outputs).
5. Print and describe what is inside `km`.
6. What are the coordinates of the centers of the clusters (called also prototypes or centroids) ?
7. Plot the data (`Yellow.cards` vs `Points`). Color the points corresponding to their cluster.
8. Add to the previous plot the clusters centroids and add the names of the observations.

9. Re-run *k*-means on `pointsCards` using 3 and 4 clusters and store the results into `km3` and `km4` respectively. Visualize the results like in question 7 and 8.

How many clusters *k* do we need in practice? There is not a single answer: the advice is to try several and compare. Inspecting the ‘between_SS / total_SS’ for a good trade-off between the number of clusters and the percentage of total variation explained usually gives a good starting point for deciding on *k* (criterion to select *k* similar to PCA).

There is several methods of computing an optimal value of *k* with R code on following [stackoverflow](#) answer:  here.

10. Visualize the “within groups sum of squares” of the *k*-means clustering results (use the code in the link above).

11. Modify the code of the previous question in order to visualize the ‘between_SS / total_SS’. Interpret the results.

laliga

So far, you have only taken the information of two variables for performing clustering. Now you will apply `kmeans()` on the original dataset `laliga`. Using PCA, we can visualize the clustering performed with all the available variables in the dataset.

By default, `kmeans()` does not standardize the variables, which will affect the clustering result. As a consequence, the clustering of a dataset will be different if one variable is expressed in millions or in tenths. If you want to avoid this distortion, use `scale` to automatically center and standardize the dataset (the result will be a matrix, so you need to transform it to a data frame again).

12. Scale the dataset and transform it to a data frame again. Store the scaled dataset into `laliga_scaled`.

13. Apply `kmeans()` on `laliga` and on `laliga_scaled` using 3 clusters and 20 iterations. Store the results into `km.laliga` and `km.laliga_scaled` respectively (do not forget to set a seed)

14. How many observations there are in each cluster of `km.laliga` and `km.laliga_scaled` ? (you can use `table()`). Do you obtain the same results when you perform `kmeans()` on the scaled and unscaled data?

PCA

15. Apply PCA on `laliga` dataset and store you results in `pcalaliga`. Do we need to apply PCA on the scaled dataset? Justify your answer.

16. Plot the observations and the variables on the first two principal components using `biplot()` function.

17. Redo the biplot (but with the `plot()` function) with colors indicating the cluster assignments.

18. Recall that the figure of question 17 is a visualization with PC1 and PC2 of the clustering done with all the variables, not just PC1 and PC2. Now apply the `kmeans()` clustering with only the first two PCs. Visualize the results and compare with the question 17.

By applying *k*-means only on the PCs we obtain different and less accurate result, but it is still an insightful way.

Implementing k-means

In this part, you will perform k -means clustering manually, with $k = 2$, on a small example with $n = 6$ observations and $p = 2$ features. The observations are as follows.

Observation	X_1	X_2
1	1	4
2	1	3
3	0	4
4	5	1
5	6	2
6	4	0

- 19.** Plot the observations.
- 20.** Randomly assign a cluster label to each observation. You can use the `sample()` command in R to do this. Report the cluster labels for each observation.
- 21.** Compute the centroid for each cluster.
- 22.** Create a function that calculates the Euclidean distance for two observations.
- 23.** Assign each observation to the centroid to which it is closest, in terms of Euclidean distance. Report the cluster labels for each observation.
- 24.** Repeat **21** and **23** until the answers obtained stop changing.
- 25.** In your plot from **19**, color the observations according to the cluster labels obtained.

Chapter 8

Hierarchical Clustering

In the last chapter we introduced the k -means algorithm. One potential disadvantage of k -means clustering is that it requires us to prespecify the number of clusters k . Hierarchical clustering is an alternative approach which does not require that we commit to a particular choice of k . Hierarchical clustering has an added advantage over k -means clustering in that it results in an attractive tree-based representation of the observations, called a *dendrogram*.

The most common type of hierarchical clustering is the agglomerative clustering (or bottom-up clustering). It refers to the fact that a dendrogram (generally depicted as an upside-down tree) is built starting from the leaves and combining clusters up to the trunk.

8.1 Dendrogram

Suppose that we have the simulated data in the following figure:

Figure 8.1: Simulated data of 45 observations generated from a three-class model.

The data in the figure above consists of 45 observations in two-dimensional space. The data were generated from a three-class model; the true class labels for each observation are shown in distinct colors. However, suppose that the data were observed without the class labels, and that we wanted to perform hierarchical clustering of the data. Hierarchical clustering (with complete linkage, to be discussed later) yields the result shown in Figure 8.2. How can we interpret this dendrogram?

Figure 8.2: Dendrogram

In the dendrogram of Figure 8.2, each leaf of the dendrogram represents one of the 45 observations. However, as we move up the tree, some leaves begin to fuse into branches. These correspond to observations that are similar to each other. As we move higher up the tree, branches themselves fuse, either with leaves or other branches. The earlier (lower in the tree) fusions occur, the more similar the groups of observations are to each other. On the other hand, observations that fuse later (near the top of the tree) can be quite different. In fact, this statement can be made precise: for any two observations, we can look for the point in the tree where branches containing those two observations are first fused. The height of this fusion, as measured on the vertical axis, indicates how different the two observations are. Thus, observations that fuse at the very bottom of the tree are quite similar to each other, whereas observations that fuse close to the top of the tree will tend to be quite different.

An example of interpreting a dendrogram is presented in Figure 8.3

Figure 8.3: An illustration of how to properly interpret a dendrogram with nine observations in two-dimensional space. Left: a dendrogram generated using Euclidean distance and complete linkage. Observations 5 and 7 are quite similar to each other, as are observations 1 and 6. However, observation 9 is no more similar to observation 2 than it is to observations 8, 5, and 7, even though observations 9 and 2 are close together in terms of horizontal distance. This is because observations 2, 8, 5, and 7 all fuse with observation 9 at the same height, approximately 1.8. Right: the raw data used to generate the dendrogram can be used to confirm that indeed, observation 9 is no more similar to observation 2 than it is to observations 8, 5, and 7.

Now that we understand how to interpret the dendrogram of Figure 8.2, we can move on to the issue of identifying clusters on the basis of a dendrogram. In order to do this, we make a horizontal cut across the dendrogram, as shown in the following Figure 8.4 where we cut the dendro4 at a height of nine results in two clusters.

Figure 8.4: The dendrogram from the simulated dataset, cut at a height of nine (indicated by the dashed line). This cut results in two distinct clusters, shown in different colors.

The distinct sets of observations beneath the cut can be interpreted as clusters. In Figure 8.5, cutting the dendrogram at a height of five results in three clusters.

Figure 8.5: The dendrogram from the simulated dataset, cut at a height of five (indicated by the dashed line). This cut results in three distinct clusters, shown in different colors.

The term hierarchical refers to the fact that clusters obtained by cutting the dendrogram at a given height are necessarily nested within the clusters obtained by cutting the dendrogram at any greater height.

8.2 The Hierarchical Clustering Algorithm

The hierarchical clustering dendrogram is obtained via an extremely simple algorithm. We begin by defining some sort of dissimilarity measure between each pair of observations. Most often, Euclidean distance is used. The algorithm proceeds iteratively. Starting out at the bottom of the dendrogram, each of the n observations is treated as its own cluster. The two clusters that are most similar to each other are then fused so that there now are $n-1$ clusters. Next the two clusters that are most similar to each other are fused again, so that there now are $n-2$ clusters. The algorithm proceeds in this fashion until all of the observations belong to one single cluster, and the dendrogram is complete.

Figure 8.6 depicts the first few steps of the algorithm.

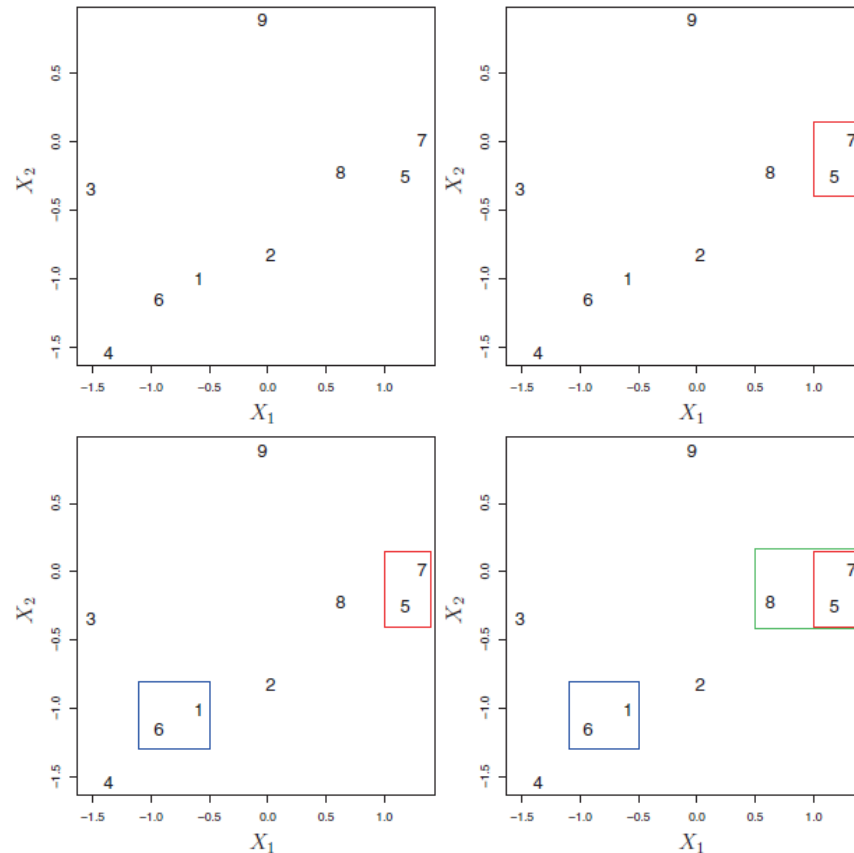

Figure 8.6: An illustration of the first few steps of the hierarchical clustering algorithm, with complete linkage and Euclidean distance. Top Left: initially, there are nine distinct clusters 1, 2, ..., 9. Top Right: the two clusters that are closest together, 5 and 7, are fused into a single cluster. Bottom Left: the two clusters that are closest together, 6 and 1, are fused into a single cluster. Bottom Right: the two clusters that are closest together using complete linkage, 8 and the cluster 5, 7, are fused into a single cluster.

To summarize, the hierarchical clustering algorithm is given in the following Algorithm:

Hierarchical Clustering:

1- Initialisation: Begin with n observations and a measure (such as Euclidean distance) of all the $C_n^2 = n(n-1)/2$ pairwise dissimilarities. Treat each observation as its own cluster.

2- For $i = n, n-1, \dots, 2$:

- (a) Examine all pairwise inter-cluster dissimilarities among the i clusters and identify the pair of clusters that are least dissimilar (that is, most similar). Fuse these two clusters. The dissimilarity between these two clusters indicates the height in the dendrogram at which the fusion should be placed.
 - (b) Compute the new pairwise inter-cluster dissimilarities among the $i-1$ remaining clusters.
-

This algorithm seems simple enough, but one issue has not been addressed. Consider the bottom right panel in Figure 8.6. How did we determine that the cluster $\{5, 7\}$ should be fused with the cluster $\{8\}$? We have a concept of the dissimilarity between pairs of observations, but how do we define the dissimilarity between two clusters if one or both of the clusters contains multiple observations? The concept of dissimilarity between a pair of observations needs to be extended to a pair of groups of observations. This extension is achieved by developing the notion of *linkage*, which defines the dissimilarity between two groups of observations. The four most common types of linkage: complete, average, single, and centroid are briefly described like

follows:

- **Complete:** Maximal intercluster dissimilarity. Compute all pairwise dissimilarities between the observations in cluster A and the observations in cluster B, and record the largest of these dissimilarities.
- **Single:** Minimal intercluster dissimilarity. Compute all pairwise dissimilarities between the observations in cluster A and the observations in cluster B, and record the smallest of these dissimilarities. Single linkage can result in extended, trailing clusters in which single observations are fused one-at-a-time
- **Average:** Mean intercluster dissimilarity. Compute all pairwise dissimilarities between the observations in cluster A and the observations in cluster B, and record the average of these dissimilarities.
- **Centroid:** Dissimilarity between the centroid for cluster A (a mean vector of length p) and the centroid for cluster B. Centroid linkage can result in undesirable inversions.

Average and complete linkage are generally preferred over single linkage, as they tend to yield more balanced dendrograms. Centroid linkage is often used in genomics.

The dissimilarities computed in Step 2(b) of the hierarchical clustering algorithm will depend on the type of linkage used, as well as on the choice of dissimilarity measure. Hence, the resulting dendrogram typically depends quite strongly on the type of linkage used, as is shown in Figure 8.7.

Figure 8.7: Average, complete, and single linkage applied to an example data set. Average and complete linkage tend to yield more balanced clusters.

8.3 Hierarchical clustering in R

Let's illustrate how to perform hierarchical clustering on dataset `laliga`.

```
# Load the dataset
laliga <- read.csv("http://mghassany.com/MLcourse/datasets/la-liga-15-16.csv", row.names=1)

# Work with standardized data
laliga_scaled <- data.frame(scale(laliga))

# Compute dissimilarity matrix - in this case Euclidean distance
```

```
d <- dist(laliga_scaled)

# Hierarchical clustering with complete linkage
treeComp <- hclust(d, method = "complete")
plot(treeComp)
```

```
# With average linkage
treeAve <- hclust(d, method = "average")
plot(treeAve)
```

```
# With single linkage
treeSingle <- hclust(d, method = "single")
plot(treeSingle) # Chaining
```

```
# Set the number of clusters after inspecting visually
# the dendrogram for "long" groups of hanging leaves
# These are the cluster assignments
cutree(treeComp, k = 2) # (Barcelona, Real Madrid) and (rest)
#ans>      Barcelona      Real Madrid Atletico Madrid      Villarreal
#ans>          1              1              1              2
#ans>      Athletic          Celta          Sevilla          Malaga
#ans>          2              2              2              2
#ans>      Real Sociedad      Betis          Las Palmas      Valencia
#ans>          2              2              2              2
#ans>          Eibar          Espanyol      Deportivo      Granada
#ans>          2              2              2              2
#ans>      Sporting Gijon Rayo Vallecano      Getafe      Levante
#ans>          2              2              2              2
cutree(treeComp, k = 3) # (Barcelona, Real Madrid), (Atlético Madrid) and (rest)
#ans>      Barcelona      Real Madrid Atletico Madrid      Villarreal
#ans>          1              1              2              3
#ans>      Athletic          Celta          Sevilla          Malaga
#ans>          3              3              3              3
#ans>      Real Sociedad      Betis          Las Palmas      Valencia
#ans>          3              3              3              3
#ans>          Eibar          Espanyol      Deportivo      Granada
#ans>          3              3              3              3
#ans>      Sporting Gijon Rayo Vallecano      Getafe      Levante
#ans>          3              3              3              3
# Compare differences - treeComp makes more sense than treeAve
cutree(treeComp, k = 4)
#ans>      Barcelona      Real Madrid Atletico Madrid      Villarreal
#ans>          1              1              2              3
#ans>      Athletic          Celta          Sevilla          Malaga
#ans>          3              3              3              3
#ans>      Real Sociedad      Betis          Las Palmas      Valencia
#ans>          3              3              3              4
#ans>          Eibar          Espanyol      Deportivo      Granada
```

```
#ans>      4      4      3      4
#ans> Sporting Gijon Rayo Vallecano      Getafe      Levante
#ans>      4      4      4      4
```

Distances `dist()`

To calculate the distance in R we use the `dist()` function. Here is a tutorial of how use it.

```
# Generate a matrix M of values from 1 to 15 with 5 rows and 3 columns
```

```
M <- matrix(1:15,5,3)
```

```
M
```

```
#ans>      [,1] [,2] [,3]
```

```
#ans> [1,]    1    6   11
```

```
#ans> [2,]    2    7   12
```

```
#ans> [3,]    3    8   13
```

```
#ans> [4,]    4    9   14
```

```
#ans> [5,]    5   10   15
```

```
# - Compute the distance between rows of M.
```

```
# - The default distance is the euclidian distance.
```

```
# - Since there are 3 columns, it is the euclidian
```

```
#      distance between tri-dimensional points.
```

```
dist(M)
```

```
#ans>      1    2    3    4
```

```
#ans> 2 1.73
```

```
#ans> 3 3.46 1.73
```

```
#ans> 4 5.20 3.46 1.73
```

```
#ans> 5 6.93 5.20 3.46 1.73
```

```
# To compute the Manhattan distance
```

```
dist(M, method= "manhattan")
```

```
#ans>      1  2  3  4
```

```
#ans> 2  3
```

```
#ans> 3  6  3
```

```
#ans> 4  9  6  3
```

```
#ans> 5 12  9  6  3
```

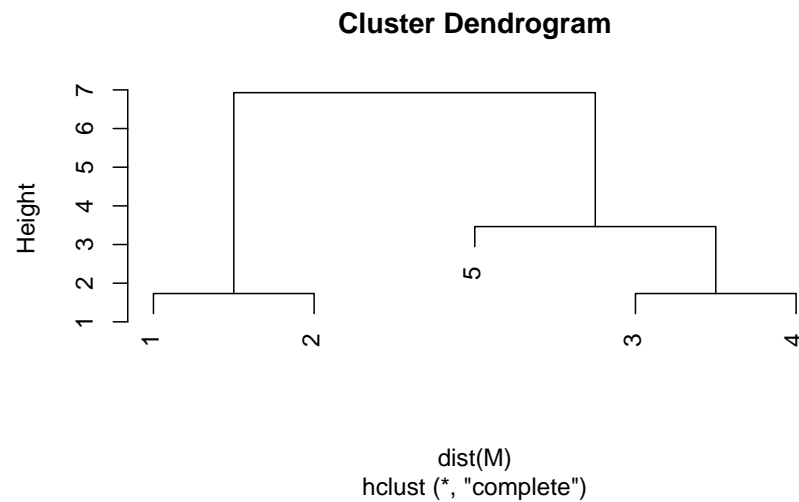

Dendrogram `hclust()`

```
# First we construct the dendrogram
```

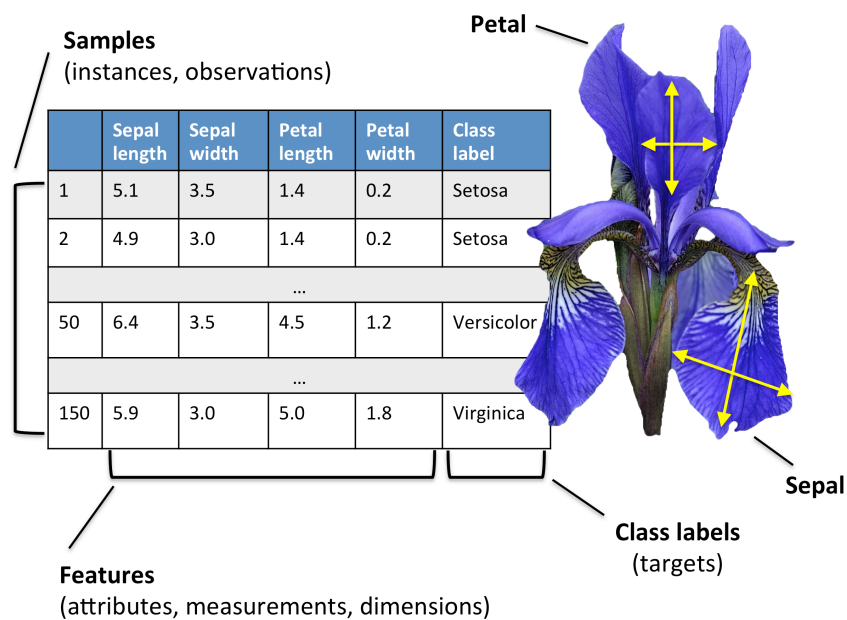

```
dendro <- hclust(dist(M))
```

```
# Then we plot it
```

```
plot(dendro)
```

Hierarchical clustering on Iris dataset

1. Download the iris dataset from  here and import it into R.
2. Choose randomly 40 observations of the iris dataset and store the sample dataset into `sampleiris`.
3. Calculate the euclidean distances between the flowers. Store the results in a matrix called `D`. (**Remark:** the last column of the dataset is the class labels of the flowers)
4. Construct a dendrogram on the iris dataset using the method average. Store the result in `dendro.avg`.

5. Plot the dendrogram.
6. Plot again the dendrogram using the following command:

```
plot(dendro.avg, hang=-1, label=sampleiris$class)
```

7. To cut the dendrogram and obtain a clustering use the `cutree`. You can choose the number of clusters you wish to obtain, or you can cut by choosing the height from the dendrogram figure. Cut the dendrogram in order to obtain 3 clusters. Store the results into vector `groups.avg`.
 8. Visualize the cut tree using the function `rect.hclust()`. You can choose the colors of the rectangles too!
 9. Compare the obtained results obtained with Hierarchical clustering and the real class labels of the flowers (function `table()`). Interpret the results.
- Bonus:** You can cut the tree manually (on demand!). To do so, plot a dendrogram first then use the function `identify()`. On the figure, click on the clusters you wish to obtain. Then hit **Escape** to finish.
10. Now apply the Hierarchical clustering on the iris dataset (the 150 observations). Choose 3 clusters and compare the results with the real class labels. Compare different methods of Hierarchical clustering (average, complete and single linkages).

Part V

Project

Final Group Project

The premise of this project is very simple. You are to pick one of the datasets below or a real dataset for which you believe there are interesting questions to answer. You will then try out all the different statistical learning approaches that we have covered in this course to try to find the best way to answer these questions. The project will be completed in groups of 2 or 3 people each.

Deliverables

This project includes two deliverables:

1. A report in `html` format, written in `R` using `RMarkdown` containing:
 - a. Members' names.
 - b. Description of the problem.
 - c. Description of the data and the question/s that you are interested in answering.
 - d. Data exploration (statistical analysis).
 - e. Review of some of the approaches that you tried or thought about trying.
 - f. Summary of the final approach you used and why you chose that approach.
 - g. Summary of the results.
 - h. Conclusions.
2. Slides for your presentation.

You can by the way use `R` to create your slides. When you create a new `RMarkdown` file, choose **Presentation** instead of **Document** on left, choose `ioslides` or `Slidy`. Here is an example and its code.

Presentation

You must submit the deliverables on Moodle. The due date for submission of both of the deliverables is Sunday **19/03/2017 23:59**.

You will present your work during the last session of this course. You will have not more than 10 minutes for your presentation.

In preparing the presentation you should be aiming it at a smart audience with statistical training to the level of multiple linear regression but not beyond. Hence, you should not just say “We did LDA” but also explain the basic idea of how it works, why it might be better than linear regression etc.

Among other things, points will be allocated for clear articulations of the question of interest, the approach you used to solve it, the reason you chose that approach, and the conclusions you were able to draw.

Datasets

Remark: You cannot choose the dataset you analyzed during Week 5.

- Adult income: Download the dataset from  here .
- Bank Marketing: Download the dataset from  here .
- Titanic: Download the dataset from  here .
- IMDB Movies: Download the dataset from  here .

You are free to use another dataset for which you believe there are interesting questions to answer. Or you can choose a dataset from the following data repositories:

- Open Gov. Data.
- Kaggle.
- KDD Nuggets.
- UCI Machine Learning Repository.
